GROUND-WATER RESOURCES OF ECTOR COUNTY, TEXAS

By

D. B. Knowles

ABSTRACT

The rock formations in Ector County that are of significance in relation to the occurrence of ground water include, from older to younger, those of the Permian system, the Dockum group of the Triassic system, the Trinity and Fredericksburg groups of the Cretaceous system, the Ogallala formation of the Tertiary system, and alluvium of the Quaternary system.

The Permian rocks generally contain only highly mineralized water. Sands and sandstones of Triassic age in general contain water of undesirable quality, although small quantities obtained from these rocks in the southwestern part of the county are used for domestic purposes. The sand of the Trinity group is the most important water-bearing formation in the county.

Water in the sand of the Trinity group occurs under water-table conditions in Ector County, and yields of wells are generally proportional to the thickness of the saturated sand. The saturated part of the sand is thin in the vicinity of Concho Bluff but thickens northeastward.

The City of Odessa operates two well fields containing a total of 72 wells that draw water from the sand of the Trinity group. The pumpage from these wells averaged 2,901,000 gallons a day in 1949. The wells are closely spaced, and, when heavily pumped, mutual interference among them results in considerable increase in the pumping lift and decrease in the yield.

The well field north of Odessa contains 66 wells. Near the center of the field the water level declined about 26 feet from September 1947 to December 1949. It is estimated that more than 14 percent of the saturated material in the well field was unwatered between the spring of 1944, when the first wells were drilled, and December 1949. The yields of some of the wells have decreased considerably.

It is believed that wells drilled in an area a few miles northeast of the Odessa well field might yield considerably more water than the present wells.

Most of the formations of the Fredericksburg group, and the Ogallala formation lie above the water table and, therefore, yield little or no water to wells. The Quaternary alluvium covers that part of the county southwest of Concho Bluff and lies directly on Triassic rocks. In the extreme northeastern part of Ector County and in northwestern Midland County, four irrigation wells that probably draw water from refilled channels of ancient Midland Draw have yields reported to range from 400 to 800 gallons a minute.

INTRODUCTION

LOCATION

Ector County is in the western part of the Midland Basin in west Texas near the southeast corner of New Mexico. It is bounded on the north by Andrews County, on the east by Midland County, on the south by Upton, Crane, and Ward Counties, and on the west by Winkler County. The intersection of longitude $102^{\circ}30'$ and latitude $31^{\circ}50'$ is near the middle of the county. The county has an area of 907 square miles. According to the United States Bureau of the Census, the population in 1950 was 42,102, of which 29,432 (70%) resided in Odessa, the county seat.

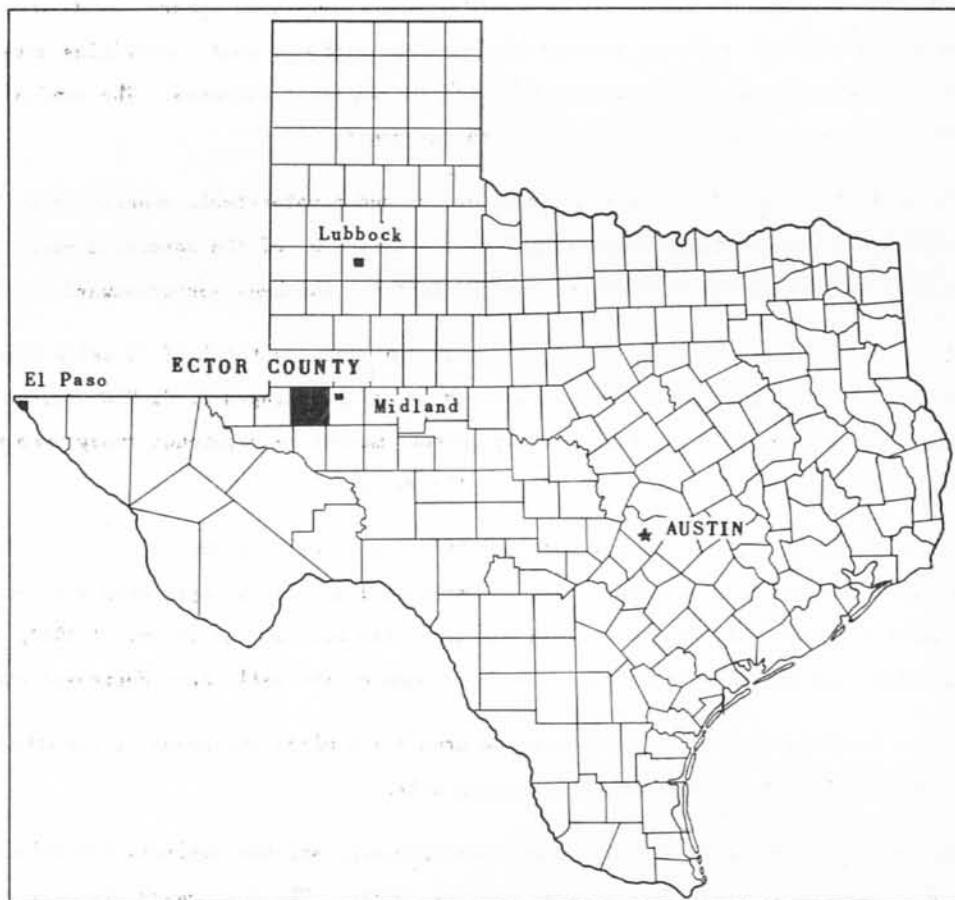

FIGURE 1.- Index map of Texas showing location of Ector County.

PREVIOUS INVESTIGATION

An inventory of water wells in Ector County was made in 1937 (Davis, 1937),^{1/} at which time the depths, diameters, depths to water, use of water, and other records were obtained. Samples of water were collected from many of the wells for chemical analysis.

PURPOSE AND SCOPE OF THIS INVESTIGATION

The investigation of the ground-water resources of Ector County was begun in the fall of 1947 as a part of the State-wide cooperative program by the Texas Board of Water Engineers and the United States Geological Survey. It was interrupted several times by work relating to other projects and was not completed until 1949. The purpose of the investigation was to obtain basic data relating to the quantity and quality of the ground water available in Ector County, with special reference to the availability of large supplies for municipal or other large-scale use.

The report includes a part of the records collected by Davis in 1937 and the data obtained during the present investigation. It includes records of 419 wells, drillers' logs of 188 wells, and chemical analyses of water from 171 wells. The locations of these wells are shown on plate 1. Logs and surface altitudes of several hundred seismograph shot holes and a few water wells were used to contour the surface of the redbeds of the Dockum group (pl. 2).

The work was done under the general direction of A. N. Sayre, chief of the Ground Water Branch, U. S. Geological Survey and under the supervision of W. L. Broadhurst, district geologist in charge of ground-water work in Texas.

AGRICULTURAL AND INDUSTRIAL DEVELOPMENT

Agriculture is limited primarily to the raising of cattle and sheep in Ector County. The U. S. Department of Agriculture reported that 13,304 cattle, 2,150 sheep, and small numbers of other livestock were raised in 1945. Only 1,410 acres of land, planted mostly in grain sorghum and truck crops, were tilled in 1944.

Ector County which produced 48,317,906 barrels of oil in 1949, ranked second in Texas oil production that year. The total produced in the county from 1926, when oil was discovered, through 1949 was 402,703,893 barrels. Other major industries include the production or manufacture of carbon black, gasoline, and oil-field supplies and equipment.

ACKNOWLEDGMENTS

The writer thanks the many persons who contributed information for this report. Representatives of oil companies furnished logs of the several hundred seismograph shot holes which were used in the preparation of plate 2. The City of Odessa determined altitudes of many water wells that were used in preparing figure 5 and assisted in other ways during the investigation. Special thanks are due A. L. Wright, municipal water superintendent, for his assistance and cordial cooperation during the investigation. The owners of private wells contributed much of the well information in this report.

TOPOGRAPHY

Ector County lies at the southern end of the High Plains. The land surface is broken by a prominent westward-facing escarpment, known as Concho Bluff, which extends southeastward across the western part of the county. (See pl. 1.) Concho Bluff owes its prominence to the erosion-resistant caliche, limestone, and sandstone exposed along its face.

The eastern part of the county, which is on the Plains, is generally rolling. Many small depressions and some shallow draws are present. Midland Draw and Monahans Draw, which flow southeast are the most prominent drainageways but carry water only after heavy rains. Much of the storm runoff collects in the numerous depressions to form ponds, which range from 5 to 40 feet in depth, and from a few hundred feet up to about a mile in diameter.

An undulating alluvial plain lies west of Concho Bluff. It is broken by sand hills along the western county boundary, where dune topography is prevalent. Many small gullies head along Concho Bluff, but elsewhere in the area only a few shallow draws, which drain southwestward, are present. The loose material composing the plain absorbs most of the rain; therefore, it has not been extensively eroded by surface runoff.

PRECIPITATION

The average annual rainfall in Texas decreases from east to west. Ector County is in the semiarid part of the State. No precipitation station is maintained in the county, but the records from a U. S. Weather Bureau station at Midland, about 20 miles northeast of Odessa, show that the minimum yearly rainfall during the period of record was 5.52 inches in 1917 and the maximum was 29.34 inches in 1920. The average precipitation for 31 years of complete record during the period 1885-1950 was 16.35 inches. It is estimated that the average annual rainfall in Ector County is about 15 to 16 inches.

The available records of rainfall at Midland, compiled from reports of the U. S. Weather Bureau, are given in the following table.

GENERAL GEOLOGY

The geologic formations that crop out in Ector County range in age from Cretaceous to Recent. The following table lists the principal subdivisions, their chief composition, and their water-bearing properties. Those listed below the Cretaceous do not crop out but are penetrated by some wells.

Table 2.- Water-bearing formations in Ector County, Tex.

System	Subdivision	Character of rocks	Thickness (feet)	Water supply	Remarks
Quaternary	Pleistocene and Recent	Caliche, sand, gravel, and clay	0-125	Yields only small quantities of water to wells except in Midland and Monahans Draws where valley fill of possible Pleistocene age yields large quantities of water to a few wells	Lies directly on Triassic rocks southwest of Concho Bluff
Tertiary	Pliocene (Ogallala formation)	Caliche, sandy clay, and sand	0-60	Yields meager quantities of water to wells	In general lies above the water table
Cretaceous	Fredericksburg group	Clay, limestone, and shell aggregate	0-75	Yields meager quantities of water to wells	In general lies above the water table
	Trinity group	Clay, fine-to medium-grained sand, and gravel	0-125	Generally yields moderate quantities of water to wells, except near Concho Bluff	Principal source of water in Ector County
Triassic	Dickinson group	Red shale interbedded with sandstone and conglomerate	700-1,600	Generally contains highly mineralized water. In places in southwestern Ector County it yields small quantities of potable water to wells	Commonly known as redbeds
Permian	Undifferentiated	Rock salt, anhydrite, red shale, sandstone, limestone, and conglomerate	5,000+	No wells draw from these rocks; water in them probably is highly mineralized	

GEOLOGIC STRUCTURE

Ector County lies in the southern part of the large structural Permian Basin or geosyncline that covers much of western Texas, eastern New Mexico, and parts of Oklahoma and Kansas. A south-trending structural "high," to which Cartwright (1930, p. 970) applied the name Central Basin Platform, lies in the southern part of the basin. This platform, which has a width of 30 to 35 miles and a length of at least 150 miles, divides the southern Permian Basin into two sub-basins, the Delaware Basin to the west and the Midland Basin to the east. Ector County lies in the extreme western part of the Midland Basin. The rocks of Cretaceous age and younger are nearly flat, but the older rocks show complex structural features at depth.

The ground-water reservoirs that contain usable water lie above the Permian rocks. Two geologic sections (fig. 2, A-A', and B-B') show the structure on the top of the Permian salt and the top of the Triassic rocks. These cross sections are from sample logs of oil tests furnished by oil companies; the drillers' logs of these oil tests are given in table 5.

GEOLOGIC FORMATIONS AND THEIR WATER-BEARING PROPERTIES

PERMIAN SYSTEM

The rocks of the Permian system are not exposed in Ector County but have been encountered in drilling for oil. Oil is produced from several zones in the Permian rocks within the county. The total thickness of these rocks is more than 5,000 feet. The upper Permian rocks closely resemble the overlying Triassic rocks, and the contact between the two systems is not always distinguishable from drillers' logs. However, the deep maroon color characteristic of the Triassic shales is rare in the Permian.

No wells were found in the county that draw water from the Permian rocks, but on the basis of the water found in them in other counties, it is believed that the water contained in these rocks is highly mineralized.

TRIASSIC SYSTEM

DOCKUM GROUP

The Triassic system is represented by rocks of the Dockum group. According to the geologic map of Texas (U. S. Geol. Survey, 1937), rocks of the Dockum group are not exposed in Ector County, but they are generally encountered beneath the surface at depths of less than 200 feet. They lie unconformably upon the uneven and eroded surface of the Permian rocks and range in thickness from about 700 to 1,600 feet. The group consists chiefly of variegated shale interbedded with sandstone and conglomerate. The most persistent beds of sandstone and conglomerate occur near the base.

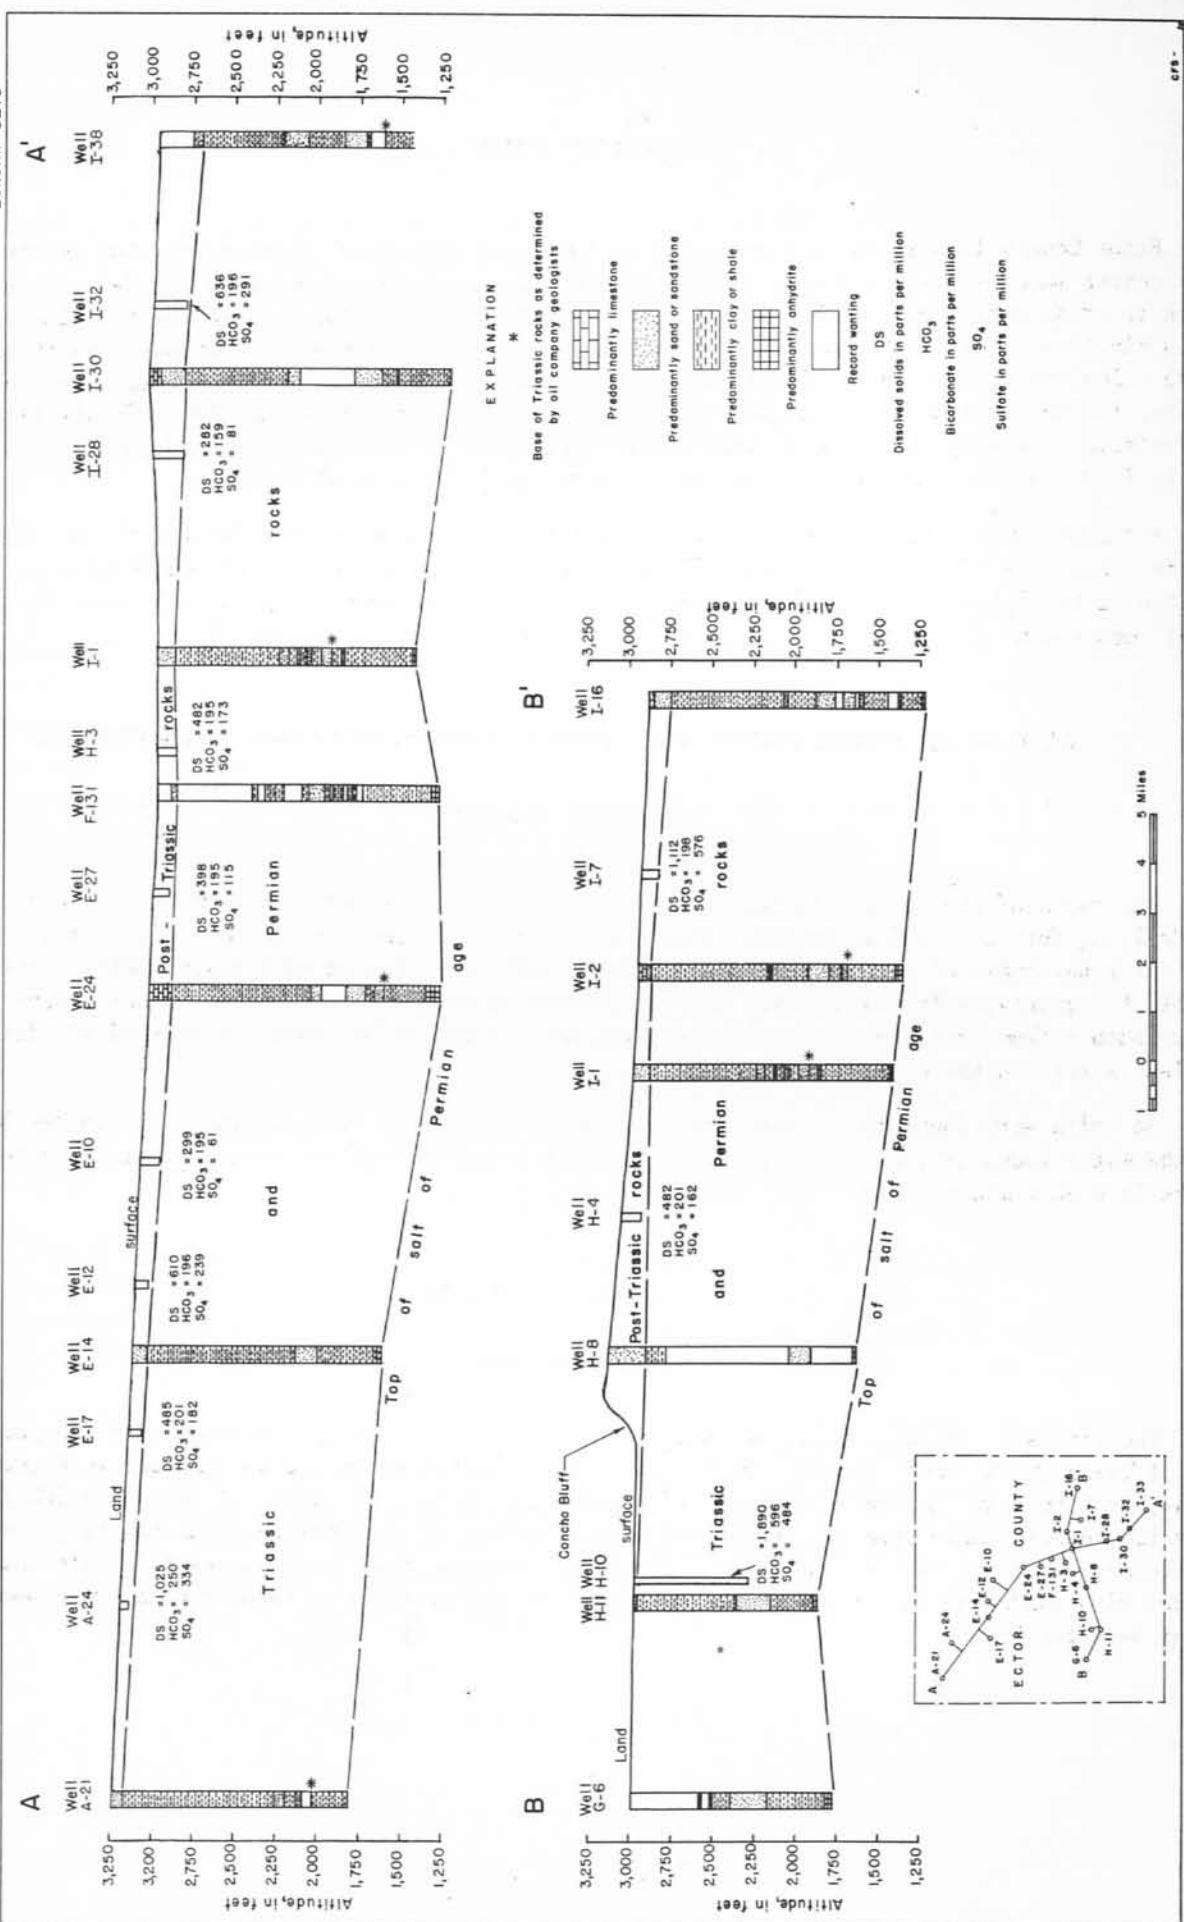

FIGURE 2.-Geologic sections in Ector County, Tex.

Study of the available data indicates that only small quantities of water are available from the Dockum group in the county and that the water is too highly mineralized for most uses. A few wells, which range in depth from 431 to 710 feet, obtain mineralized but usable water from these rocks in the southwestern part of the county.

CRETACEOUS SYSTEM

TRINITY GROUP

A sand and gravel was deposited on the eroded surface of older rocks as the sea advanced northward and northwestward across Texas in Cretaceous time. The sand has the appearance of a single stratigraphic unit, although it becomes progressively younger toward the northwest. Hill (1901) has discussed this subject at some length.

The Trinity group in Ector County lies unconformably on an eroded surface of Triassic rocks. It is exposed along the edge of Concho Bluff in the southwestern part of the county and in a narrow east-west belt a few miles north of Odessa. The exposed sediments along Concho Bluff average about 75 feet in thickness. They consist of a green clay, probably lying directly on the Triassic rocks, gray sand and gravel, and fine-grained yellow sand. In Ector County these deposits are the only representative of what is known farther east as the Trinity group and are probably equivalent to the Paluxy sand of that group. In some places the sand has the appearance of hard sandstone or quartzite and forms erosion-resistant ledges along Concho Bluff. The sand yields more water of acceptable quality than any other water-bearing formation in the county, but owing to the relatively thin saturated section and low permeability only moderate quantities of water are obtained from individual wells. The yields of individual wells range from a few gallons a minute near Concho Bluff to about 300 gallons a minute north and northeast of Odessa.

FREDERICKSBURG GROUP

The Fredericksburg group of central Texas has been divided into four formations which, in ascending order, are the Walnut clay, the Comanche Peak limestone, the Edwards limestone, and the Kiamichi formation. However, no effort will be made in this report to classify the rocks of the Fredericksburg group into formations, because they are not important sources of water.

The Fredericksburg group lies conformably on the Trinity group throughout the area east of Concho Bluff. The group, which consists mostly of yellow clay, white and yellow limestone, and shell aggregate is about 40 feet thick. The rocks are exposed in the north-central part of the county and along Concho Bluff, which owes much of its prominence to the hard, erosion-resistant limestone. Most of the rocks of the group lie above the water table; therefore, little ground water is to be found in them although the water that is present is of acceptable quality.

TERTIARY SYSTEM**OGALLALA FORMATION**

The Tertiary system is represented in Ector County by remnants of the Ogallala formation which cover much of the county east of Concho Bluff. The Ogallala rests unconformably upon rocks of the Fredericksburg group and consists of caliche, sandy clay, and sand. It is probably not more than 60 feet thick throughout most of the county and in general lies above the water table. In local areas where the Ogallala lies below the water table, the water is of satisfactory quality, but the quantities that can be expected from wells are small.

QUATERNARY SYSTEM

The Quaternary rocks cover the older rocks in that part of the county southwest of Concho Bluff. They lie unconformably upon an eroded surface of Triassic rocks and form a rolling alluvial plain, except in the extreme western part of the county where sand hills are prevalent. The deposits consist mostly of sand, clay, and gravel which were derived partly from erosion along Concho Bluff, but the sand hills along the western county boundary probably migrated by wind action from the west.

The Quaternary sand and gravel generally contain only thin sections of saturated material and yield only small quantities of water to wells. Only a few wells in the county draw water from these rocks, and the analyses of samples from them show that the water is of poor quality.

In the northeastern part of the county, the valley fill in Midland Draw and Monahans Draw probably is of Pleistocene age and may be the source of relatively large quantities of water. For example, well C-32 was reported to yield about 500 gallons a minute in October 1948. Three other wells located in Midland County three-fourths of a mile to 4 miles east of well C-32, are reported to have yields ranging from 400 to 800 gallons a minute.

DEVELOPMENT OF WATER FROM WELLS

In many parts of western Texas, particularly in the High Plains, depressions in the surface of pre-Tertiary rocks have been filled with sand, thus locally providing thicker sands which yield proportionately greater quantities of water to wells. These depressions are in the form of buried stream channels or circular depressions known as sink holes. The more recent alluvium and windblown material have obscured the ancient topography so that the present relatively smooth surface presents little indication of the locations of the more favorable ground-water reservoirs.

Several oil companies have done seismograph exploration work in Ector County and have generously cooperated by furnishing logs of shot holes. It was hoped that a definite subsurface drainage pattern might be revealed by drawing contours on the surface of Triassic redbeds.

The attempt to contour the redbed surface was only partially successful and the contours shown on plate 2 are presented to show only in a general way where depressions may be found and thus to point out the areas that may be favorable for prospecting for water. The accuracy of the contours is limited by the accuracy of the logs of the shot holes. Because the character of the material above the redbeds is almost entirely unrelated to the occurrence of oil and because the recording of such data delays drilling operations, drillers are not generally required to record accurate logs of shot holes. Red clays or sands are generally logged as redbeds. Clay or shale beds of various shades of red are found in many of the formations ranging in age from Permian to Recent. In some places, the Triassic clays are blue or green and contain no fossils. Even where cuttings are available for study it is difficult for geologists to identify or classify the formations.

SOUTHWEST OF CONCHO BLUFF

The part of Ector County southwest of Concho Bluff includes grid-area G and the southwestern parts of areas D, H, and I, (shown in pl. 1). All the ground water is obtained from Quaternary alluvium or from sand of Triassic age. The water is used principally for stock and in drilling test wells for oil. The approximate altitude of the base of the Quaternary alluvium is shown in plate 2 and figure 3-A. The thickness of the alluvium varies considerably from well to well. For example, 49 feet of gravel was reported in the log of well G-1 but no sand or gravel in the log of well G-5. Meager data indicate that much of the permeable material penetrated by wells that draw from the alluvium probably lies above the water table. The map (pl. 2) also shows many depressions in the surface of the Triassic rocks. Larger quantities of water may be available in the depressions, owing to the increased thickness of saturated material. Few wells that draw water from the alluvium penetrate the entire saturated section, but an attempt was made to estimate the saturated thickness from available logs of seismograph shot holes close to water wells. It was found from this comparison that the saturated alluvium ranged from as little as 8 feet in well H-14 to as much as 41 feet in well H-30. Cross section C-C' in figure 3-A shows the apparent thickness of the alluvium in an east-west direction across this area.

The water from the alluvial sand is generally of poor chemical quality. The analyses of water from six wells show a range in dissolved solids from 1,180 to 3,440 parts per million and in sulfate from 646 to 1,970 parts per million. No water from wells in the alluvium is used for domestic supply.

Water is obtained from sands in the Dockum group by 10 wells in the area, which range in depth from 431 to 710 feet. Each well for which a record is available is reported to yield less than 20 gallons a minute. Only well H-18 is used for domestic purposes, and it supplies about 30 families in the vicinity of Penwell.

The water from wells drawing from the Triassic sands also is of poor chemical quality. The analyses of water from six wells show a range in dissolved solids from 1,890 to 7,190 parts per million, in sulfate from 484 to 2,440 parts per million, and in chloride from 240 to 2,710 parts per million.

MAY 1952

NORTHEAST OF CONCHO BLUFF
MUNICIPAL SUPPLY OF ODESSA

The population of Odessa increased from 9,573 in 1940 to 29,432 in 1950. Consequently the requirements for municipal water supply increased from 602,000 gallons a day in 1940 to 2,901,000 gallons a day in 1949. Prior to 1944 about 40 wells had been drilled within the city limits to depths ranging from 100 to 140 feet. Of these wells 29 were still in use in 1943. The wells were reported to have had initial yields that ranged from 100 to 125 gallons a minute. As pumping continued year after year, the yields decreased until at the end of 1943 none of the wells was yielding more than 30 gallons a minute. Some of the wells were abandoned in 1944 and by the end of 1949 none were in use.

In the spring of 1944 the City began developing a new well field about 2 miles north of Odessa. The field was extended northward as the water requirements increased, and by December 1949 it had 66 wells.

The municipal wells north of Odessa penetrate the entire section of the Trinity group. Short production tests were made on most of the wells by the driller as the wells were completed. Data from the tests on 57 wells indicate initial yields ranging from 35 to 310 gallons a minute and averaging 167 gallons a minute. The specific capacities ranged from 1.0 to 8.6 gallons a minute per foot of drawdown and averaged 3.1 in 39 of the wells.

Chemical analyses of water from six representative wells (F-46, F-60, F-82, F-92, F-135, and F-141) show a range in dissolved solids from 342 to 877 parts per million, in sulfate from 44 to 255 parts per million, and in bicarbonate from 186 to 229 parts per million. The water is relatively hard; however, it is of satisfactory quality for nearly all uses. The water is chlorinated and delivered to the distribution system without further treatment.

In 1948 an additional well field containing six wells (I-10 to I-15) was developed at the southern edge of Odessa and adjacent to Monahans Draw. The driller's logs of these wells show depths ranging from 120 to 125 feet and sand or sand and gravel ranging in thickness from 77 to 87 feet and averaging about 82 feet. The water levels in wells I-10, I-11, and I-12 were reported to be 30, 22, and 29 feet below the land surface, respectively, in August 1948. Wells I-10 and I-11 yielded 164 and 243 gallons a minute, respectively during short production tests when they were completed. It is reported that in well I-9, about 1,300 feet north of well I-10, the drawdown was 46 feet after the well was pumped at 146 gallons a minute for 1 hour, indicating a specific capacity of about 3.2 gallons a minute per foot of drawdown.

In December 1948 the City drilled two test wells (F-117 and F-118) in sections 31 and 25, blocks 41 and 42, T. 2 S., 2 and 3 miles, respectively, east of Odessa. The test well in section 31 was drilled to a depth of 110 feet, but no important water sands were penetrated below 75 feet. The static water level was 26.7 feet below the land surface. The well yielded 50 gallons a minute with 38 feet of drawdown after pumping 1 hour. The test well in section 25 was drilled to a depth of 125 feet and penetrated water sands to a depth of 118 feet, at which depth shale, presumably of Triassic age was encountered. The water level was 56.0 feet below the land surface.

The well was pumped for 23 hours and yielded 56 gallons a minute with a drawdown of 41 feet. The water from well F-117 contained 482 parts per million of dissolved solids, 87 parts per million of sulfate, and 238 parts per million of bicarbonate. The water from well F-118 contained 377 parts per million of dissolved solids, 70 parts per million of sulfate, and 220 parts per million of bicarbonate. The logs of these wells are given in table 5.

The test wells in sections 25 and 31 showed lesser thicknesses of saturated material and smaller yields than the public-supply wells north of Odessa. As a result of those tests, the City did not attempt to develop a well field at those sites but extended the north well field farther north of the city. A study of available drillers' logs in the vicinity of the test wells confirms the decision that wells probably cannot be developed east of Odessa with yields comparable to those of the present public-supply wells.

PUMPING AND ITS EFFECT ON THE WATER TABLE

The average daily pumpage by the City of Odessa for the first 11 months of 1949 was more than six times that in 1938. Table 3 gives the average daily pumpage by months for the 12-year period 1938-49. The average daily pumpage by years is shown graphically in figure 4.

A map of the water table north of Odessa in parts of grid areas C and F is shown in figure 5. The map indicates that the slope of the water table in the unpumped areas is about 6 to 7 feet per mile to the southeast. A depression has developed in the water table in and adjacent to the city well field, owing to the heavy withdrawals there since 1944, showing that a considerable volume of formerly saturated material has been unwatered. Livingston and Lang (1943, p. 9) determined the specific yield of the sand of the Trinity group at the Army flying school, about 10 miles northeast of Odessa, to be about 15 percent. If this figure is applicable to the sand of the Trinity group in the Odessa well field, the volume of material unwatered during the year 1949 by the reported withdrawal of about 1 billion gallons of water would be about 20,000 acre-feet, assuming no recharge to the water-bearing sand.

Study of drillers' logs and reported water levels in 29 wells shows that the saturated thickness of the sand of the Trinity group in the well field north of Odessa ranged from 63 to 128 feet and averaged 97 feet when the wells were drilled. Water levels in 48 wells in 1949 show that the saturated thickness ranged from 56 to 114 feet and averaged 83 feet. This indicates an apparent reduction of about 14 percent in the amount of water in storage.

The unwatering of the sand is accompanied by an increase in the pumping lift and a decrease in yield. The city wells are closely spaced, which causes an additional increase in the pumping lift due to the merging of the cones of depression. Wells F-45, F-47, F-49, and F-50 were reported to have had yields of 167, 159, 230, and 150 gallons a minute, respectively, when they were drilled in the spring of 1944. The yields of these wells in October 1947 were 69, 75, 41, and 46 gallons a minute, respectively.

a/ Based on pumpage for first 11 months of 1949.

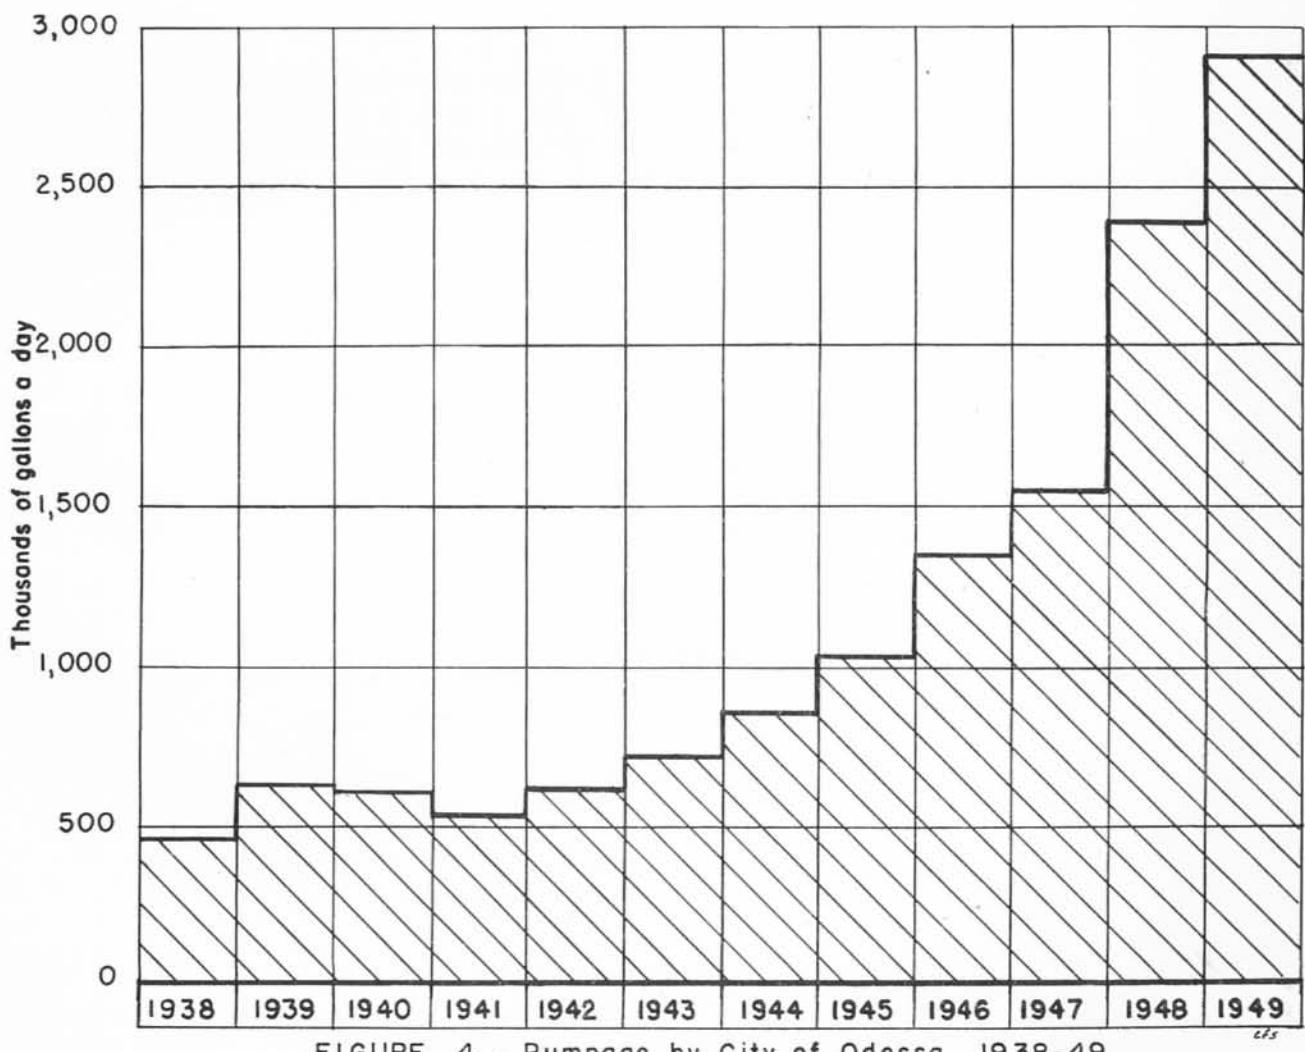

FIGURE 4. - Pumpage by City of Odessa, 1938-49.

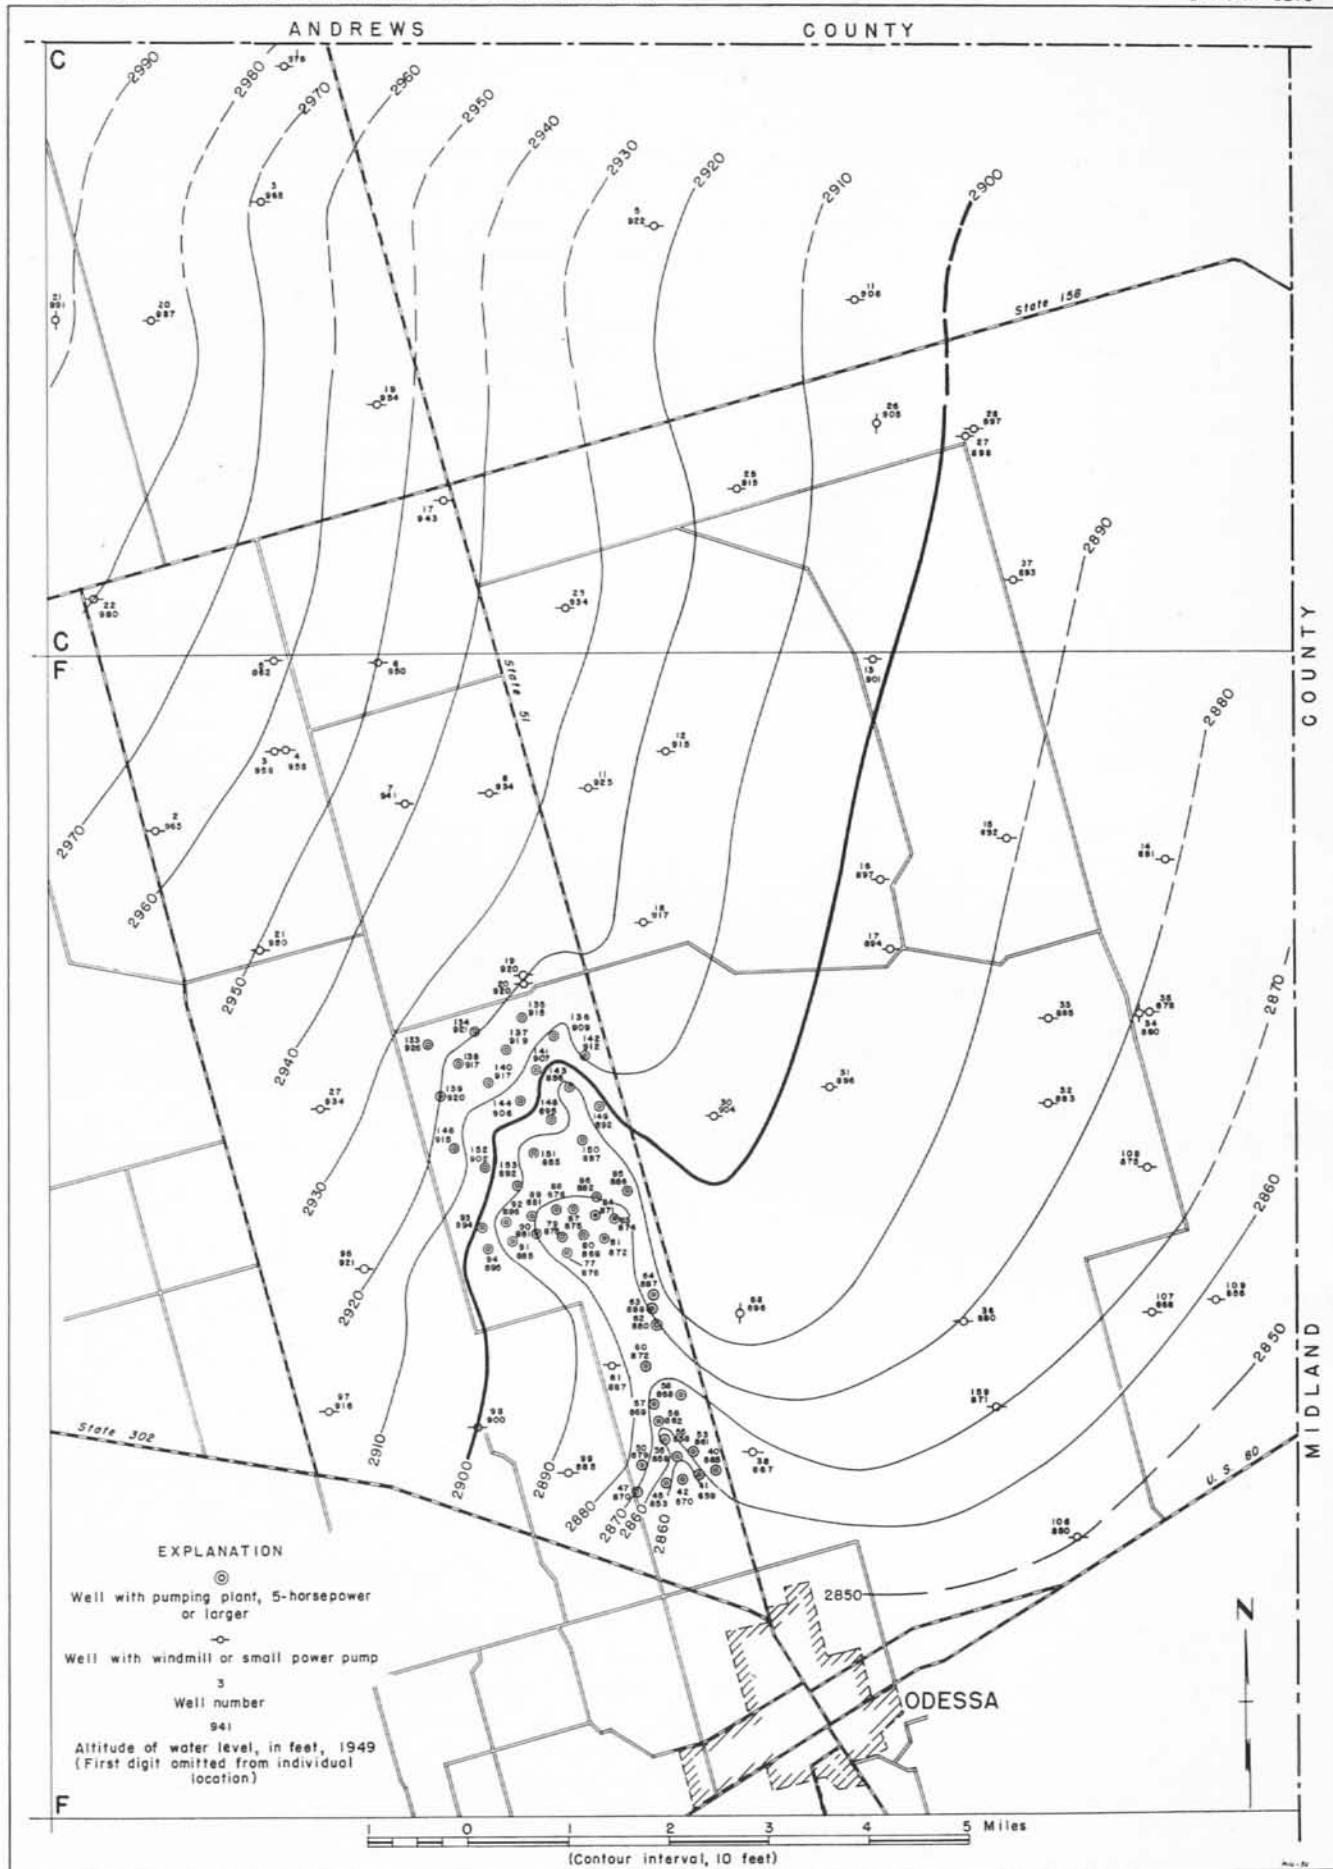

FIGURE 5.-Altitude of water table north of Odessa, Ector County, Tex.

Comparison of water-level measurements in the city well field north of Odessa made in September 1947 and December 1949 show a maximum rise of 5.1 feet in well F-47 in the extreme southwestern part of the well field and a maximum decline of 36.7 feet in well F-84 in the central part of the well field, where the wells are very closely spaced. The measurements are not strictly comparable, however, because more wells were idle for a longer period in December 1949 than in September 1947. After a well has been pumped for a long period and then shut down, the water level may continue to rise for several months. The declines would be larger, and the rises smaller, from 1947 to 1949 if the wells had been idle for comparable periods in the two years. The wells in the southern part of the well field in sections 4 and 9, block 42, T.2 S. showed rises or small declines from September 1947 to December 1949. These wells were among the first drilled and their yields have declined the most. As a result, they are pumped only when water requirements are large, and the present amount of pumping appears to be approximately balanced by lateral movement of water from adjacent areas.

A hydraulic gradient from all directions is established toward a well when pumping begins. Under water-table conditions, water is obtained for a short time by unwatering the saturated material around the well. As pumping continues, water moves toward the well from increasingly greater distances and the water level near the well declines at a much slower rate than when pumping began. However, so long as the amount of water percolating to a discharging well remains constant, the hydraulic gradient toward the well must be continuously steepened. The drawdown in the well must be increased if the hydraulic gradient is steepened. In order to obtain a moderately large yield from a well in the sand of the Trinity group in Ector County, it becomes necessary to steepen the hydraulic gradient so that the pumping level is near the bottom of the sand soon after pumping begins. After this pumping level has been reached it is not possible to steepen the hydraulic gradient, and the yield of the well must necessarily decrease.

OTHER DEVELOPMENT

Many of the wells in the area northeast of Concho Bluff supply water for domestic use and stock on the farms and ranches. They are equipped with windmills or small power pumps and yield only a few gallons a minute each. Most of these wells do not fully penetrate the water-bearing sand because only small yields are required. They produce from the sands of the Trinity group, but some of those adjacent to the draws may also obtain water from Quaternary rocks. The water, with some exceptions, is of satisfactory quality for most uses. It appears to be more highly mineralized, especially with respect to sulfate content, adjacent to the draws than elsewhere.

GOLDSMITH AREA

An oil camp, about a mile east of Goldsmith in the northwestern part of the county, is supplied by four wells in the sand of the Trinity group, E-3, E-4, E-5, and E-6. The water levels in wells E-4 and E-6 are reported to have been 100 and 97 feet below the land surface, respectively, in 1947. These wells were reported to yield about 60 gallons a minute each after a few hours of pumping. These data and the driller's logs of wells E-4 and E-6 indicate a thickness of saturated sand of 37 and 32 feet, respectively. The driller's logs show greater thicknesses of sand above the water table than below it. It is probable that wells with large yields cannot be developed in the immediate vicinity of these wells.

A rather large amount of water is pumped from wells, drawing from sands of the Trinity group, in an area extending about 3 to 6 miles north from Goldsmith. Wells are used to supply water for a gasoline plant, for the drilling of oil tests in the surrounding area, and for domestic use in the oil camps and the town of Goldsmith. The yields of seven of these wells (B-23, B-24, B-41, B-42, B-43, B-44, and B-45) are reported to range from 58 to 200 gallons a minute and to average about 115 gallons a minute. The drillers' logs and available water-level data indicates 59, 61, and 35 feet of saturated sand in wells B-41, B-42, and B-45, respectively. The water is moderately hard but is of satisfactory quality for most uses. Chemical analyses of water from wells B-17, B-21, B-22, B-28, B-35, B-43, and B-44 show a range in dissolved solids from 352 to 477 parts per million, in sulfate from 50 to 104 parts per million, and in bicarbonate from 152 to 206 parts per million.

NORTHEAST OF ODESSA

Plate 2 indicates an elongated trough or buried stream valley in the extreme northeastern part of the county. This stream valley has an eastward trend and is of varying width. Figure 3-B shows three cross sections (D-D', E-E', and F-F') constructed approximately at a right angle to the axis of the stream valley. Cross sections D-D' and F-F' show some expression of the stream valley at the surface and much greater relief at the base of the sands. It appears probable that coarser sediments were deposited in the buried stream channels than elsewhere. The water-bearing sands, therefore, may be more permeable than in the vicinity of the Odessa well field. Wells with larger yields than from the present city wells might be developed in this area if the thickness of the saturated material is comparable to that in the Odessa well field. The thickness of the saturated valley fill can be estimated only partly from existing well logs and water-level data. The data indicate that the saturated material is about 100 feet thick in the vicinity of well C-5 and about 80 to 90 feet thick in the vicinity of well C-11, which compares favorably with saturated thicknesses in the city well field north of Odessa. The data for the northeastern part of the county are inconclusive, but it appears that the area is promising for the development of additional ground-water supplies. A comprehensive test-drilling program would be necessary to define adequately the amount of saturated material in the buried stream channel. Such a program, if undertaken, should be carried on simultaneously with a series of interference tests to determine the coefficients of permeability ^{2/} and storage ^{3/} of the sands. Such tests would make it possible to determine the most desirable well spacing and to predict the approximate decline of the water table to be expected as a result of pumping a well in the area over a period of time.

^{2/} The coefficient of permeability may be defined as the rate of flow, in gallons a day, through a cross section 1 foot high and 1 mile wide under a hydraulic gradient of 1 foot per mile at 60° F.

^{3/} The coefficient of storage may be defined as the amount of water, expressed as a fraction of a cubic foot, discharged from each vertical column of the aquifer with a base of 1 square foot as the water level falls 1 foot; for water-table conditions, it is approximately equal to the specific yield.

The quality of the water in this northeastern part of the county is not as good, however, as it is a few miles to the west and south. Analyses of water from four wells (C-4, C-6, C-10, and C-13) show a range in dissolved solids from 414 to 938 parts per million, in sulfate from 74 to 312 parts per million, and in bicarbonate from 201 to 316 parts per million. The water of poorest quality is from shallow wells.

In the northeastern part of the county near the Ector-Midland County line and immediately south of the buried stream channel, well C-32 was drilled in October 1948, as a test well for irrigation. It was reported to yield about 500 gallons a minute. An irrigation well in Midland County, about three-fourths of a mile east of well C-32, is reported to be 138 feet deep and to have had a water level 28 feet below the land surface when drilled in 1948. This well was estimated to yield about 500 gallons a minute in September 1948. Analysis of the water shows 640 parts per million of dissolved solids, 151 parts per million of sulfate, and 228 parts per million of bicarbonate. Two other irrigation wells in Midland County, which are about $\frac{1}{2}$ and 4 miles southeast of Ector County well C-32, are reported to yield 400 and 800 gallons a minute, respectively. It is believed that these four irrigation wells are in a part of the same buried drainage system that is found in the northeastern part of Ector County.

No drillers' logs are available for water wells north and east of the Odessa well field. The water wells are used for domestic purposes and stock and few, if any, of them fully penetrate the saturated sand of the Trinity group. It is possible, however, to give the minimum thicknesses of saturated material in a few parts of the area from the depths and water-level data of some of the deeper wells. The amount of saturated material in wells F-2, F-5, C-17, C-38, F-14, F-15, F-33, and F-109 is at least 70, 95, 90, 60, 55, 65, 100, and 65 feet, respectively. These thicknesses do not necessarily represent material that will yield water to wells. They represent the material, both clay and sand, penetrated in the wells that lies below the water table. The available drillers' logs in the county east of Concho Bluff indicate that the material below the water table is predominantly sand. It is believed the area north and east of the Odessa well field offers more promise for the development of moderate supplies of ground water than any other part of the county, except the extreme northeastern part of the grid-area C. The saturated material, if predominantly sand, is comparable in thickness to that found in the Odessa well field, and it is believed that wells might yield from 100 to 200 gallons a minute or more, especially in grid-area C and the northern part of grid-area F. Any development should be preceded by a test-drilling program. The chemical character of the water, with few exceptions, is satisfactory for most uses.

SOUTHWEST OF ODESSA

The contours (see pl. 2) on the approximate base of the sand of the Trinity group in the area west and south of Odessa show few irregularities. The thickness of the saturated material can be roughly estimated at a few locations from the seismograph shot-hole logs and water-level data. It is estimated that the thickness of saturated material in wells E-22, E-25, F-27, F-96, F-97, and F-99 is about 55, 50, 85, 80, 80, 70, and 65 feet, respectively. Wells E-22 and E-25 show less saturated material than the wells in grid-area F to the east and there are indications that the saturated material thins appreciably to the west near Concho Bluff.

Near Concho Bluff, well D-18 is reported to be 190 feet deep, and the water level was 169.8 feet below the land surface in 1937. Well H-25, also near Concho Bluff, is reported to be 192 feet deep, and the water level was 183.8 feet below the land surface in 1937. It is apparent that the water-bearing section of the sand of the Trinity group along Concho Bluff and probably for a few miles east is very thin.

QUALITY OF WATER

Chemical analyses of water from wells in Ector County are given in table 6. Ground water in Ector County is used primarily for public supply, industrial supplies, and for domestic and stock supplies on the farms and ranches.

It is not possible to define exact limits of mineralization beyond which water cannot be used for particular purposes. Water used for domestic and municipal supplies, wherever possible, should conform to the standards of the United States Public Health Service (1946) for use on interstate carriers. These standards place the following limits on the more important minerals ordinarily found in solution.

Iron (Fe) and manganese (Mn) together should not exceed 0.3 part per million.

Magnesium (Mg) should not exceed 125 parts per million.

Chloride (Cl) should not exceed 250 parts per million.

Sulfate (SO_4) should not exceed 250 parts per million.

Dissolved solids should not exceed 500 parts per million, for a water of good chemical quality. However, if such water is not available, a dissolved solids content of 1,000 parts per million may be permitted.

The wells west of Concho Bluff yield water that is somewhat highly mineralized. Wells that draw from Quaternary alluvium are used only for stock supplies. The analyses of water from six of these wells show a range in dissolved solids from 1,180 to 3,440 parts per million. One of the wells that draws from the deeper Triassic rocks is used for domestic supply. The analysis of the water from this well shows 1,940 parts per million of dissolved solids. The available analyses indicate that wells drawing from the Triassic rocks yield water that, in general, has a higher chloride content than wells drawing from the Quaternary alluvium.

The wells east of Concho Bluff, which include the well fields of the City of Odessa, draw principally from sands of the Trinity group. The water from most of the wells contains less than 1,000 parts per million dissolved solids. The water from the wells used by the City of Odessa generally conform to the standards of the United States Public Health Service. Many of the wells yield water containing less than 500 parts per million dissolved solids. The water is satisfactory for most purposes although it is somewhat hard. The chemical character of the waters from most of the wells east of Concho Bluff is very similar. It was not found feasible to differentiate the wells that draw from sands of the Trinity group from those that may possibly draw from younger rocks on the basis of the chemical character of the water.

The quality of water in different parts of Ector County is discussed briefly in the section "Development of water from wells".

SUMMARY AND CONCLUSIONS

West of Concho Bluff only meager supplies of ground water are available. The saturated part of the Quaternary alluvium is thin and small yields are to be expected from wells. The water in the alluvium is moderately to highly mineralized. Wells drawing from the underlying Triassic rocks range in depth from 431 to 710 feet. These rocks can be expected to yield only small quantities of water, because of the low permeability. The water in them is moderately to highly mineralized.

East of Concho Bluff the principal water-bearing formation is the sand of the Trinity group. The overlying limestone of the Fredericksburg group and the Ogallala formation of Tertiary age probably are not saturated except along the draws where the depth to water is slight. The underlying Triassic rocks offer no promise for the development of a ground-water supply. The base of the Trinity group is generally not more than 200 feet beneath the land surface. The saturated section of the sand is thin along Concho Bluff, but it thickens to the east and is believed to be thickest north and east of Odessa.

The saturated sand averaged 83 feet in thickness in the Odessa well field north of the City in 1949 and probably averaged about 100 feet prior to the heavy pumping in the well field. Because the wells were too closely spaced, the sand near them was unwatered rapidly, resulting in a decrease in the yield of the wells and an increase in the pumping lift.

The investigation revealed a buried stream channel having an eastward trend in the extreme northeastern part of the county. It is probable that the water-bearing material in the channel is coarser and may yield water to wells more readily than the sand of the Trinity group in the vicinity of Odessa. Near the Ector-Midland County line, immediately south of the buried stream channel, an irrigation well is reported to yield 500 gallons a minute. Three other irrigation wells a short distance to the southeast in Midland County are reported to yield 400 to 800 gallons a minute. The four irrigation wells are believed to be in a part of a buried drainage system that cannot be traced in detail at the surface. The area overlying the stream channel offers more promise for the development of relatively large ground-water supplies than any other part of the county. A comprehensive test-drilling program would be necessary to determine the location and saturated thickness of the deposits of sand, and their probable yield. Chemical analyses of water from wells east of Concho Bluff indicate that the water is of satisfactory quality for most purposes.
