GROUND-WATER RESOURCES OF CHAMBERS AND JEFFERSON COUNTIES, TEXAS

ABSTRACT

The hydrologic units of Chambers and Jefferson Counties, the Chicot and Evangeline aquifers and the Burkeville aquiclude, are composed of gravel, sand, silt, and clay of Miocene, Pliocene, Pleistocene, and Holocene age.

Only small quantities of fresh ground water, less than 1,000 mg/l (milligrams per liter) dissolved solids, are available in Chambers and Jefferson Counties, and these supplies are fairly well developed. In 1965, approximately 18.6 mgd (million gallons per day) of ground water was used in the report area. Of this amount 10 mgd was fresh water produced from wells in adjacent Hardin and Orange Counties. Total pumpage of fresh water in Chambers and Jefferson Counties was approximately 6.1 mgd. About 2.5 mgd was slightly or moderately saline water.

Industrial use of ground water was approximately 9 mgd, of which 4 mgd was imported. Municipal use of ground water was approximately 8 mgd, of which 6 mgd was imported from Hardin County by the city of Beaumont. Irrigation use in 1965 was approximately 1.5 mgd. Use of ground water for irrigation will remain small because most of the available water is too saline.

Two aquifers, the Chicot (including the upper and lower units), and the Evangeline, furnish fresh water to wells. Fresh water is produced from wells in the Chicot aquifer in the Mont Belvieu, Houston Point, Anahuac, Galveston Bay, and Trinity Bay areas of Chambers County; in a small strip 2 to 4 miles wide along the eastern and northern boundaries of Jefferson County; and in the Hamshire-Winnie area of Chambers and Jefferson Counties. The Evangeline aquifer produces fresh water in the Mont Belvieu and Houston Point areas of Chambers County. Salinization of water in the aquifers has occurred in the vicinity of shallow salt domes.

Additional small supplies of fresh ground water can be developed in the present producing areas. The largest undeveloped source of fresh water underlies Galveston Bay in Chambers County. Large scale increased usage of ground water will require further

importation from neighboring counties.

Most areas in both counties are underlain by very little or no fresh water, but large quantities of slightly and moderately saline ground water (1,000 - 10,000 mg/l) are present at shallow depths in all areas except in the vicinity of shallow salt domes.

Aquifer tests were made in 22 wells. Coefficients of permeability ranged from 108 to 1,670 gpd (gallons per day) per square foot. The highest permeability (1,670 gpd per square foot) was determined in a brackish-water well completed in the lower unit of the Chicot aquifer. The permeability of the sands of the Evangeline aquifer (244 and 327 gpd per square foot) approximate the permeability measured in the Houston district and in Jasper and Newton Counties.

Water levels have declined generally in both counties. The largest decline is due to pumping in adjacent Harris County. The maximum decline was estimated to be at least 150 feet in the lower unit of the Chicot aquifer in the area adjacent to Baytown in Harris County. This major decline has resulted in a land-surface subsidence of about 2 feet.

The exposed formations in Chambers and Jefferson Counties consist of Pleistocene and Holocene deposits, of which the Beaumont Clay of Pleistocene age is the oldest. Remnants of the relict Ingleside barrier island and beach system are enclosed within the Beaumont. The Deweyville deposits of Bernard (1950), which are topographically lower than the Beaumont, underlie the high terraces that border the Holocene floodplains of the Trinity and Neches Rivers. The Holocene deposits are alluvial and deltaic deposits and coastal marsh, mud flat, and beach (chenier) deposits, all comparatively low lying.

The Beaumont Clay, which is the most extensively exposed formation, is a sequence of deltaic and meander-belt deposits of the Pleistocene Trinity River. The Beaumont is probably less than 100 feet thick. On the basis of radiocarbon dating, the formation is probably more than 30,000 years old.

GROUND-WATER RESOURCES OF CHAMBERS AND JEFFERSON COUNTIES, TEXAS

INTRODUCTION

Purpose and Scope of the Investigation

The investigation of ground-water resources in Chambers and Jefferson Counties began in September 1965 as a cooperative project between the U.S. Geological Survey and the Texas Water Development Board. The purpose of the project was to determine the occurrence, availability, dependability, quality, and quantity of ground water suitable for public supply, industrial use, and irrigation.

The general scope of the investigation included the collection, compilation, and analysis of data; determination of the location and extent of the water-bearing formations; determination of the hydrologic characteristics of the water-bearing sands; a study of the chemical quality of the water; and estimates of the quantities of ground water available for development.

One section of the report presents a previously unpublished study of the Quaternary geology of the area.

Location and Extent of the Area

Chambers and Jefferson Counties are situated on the upper Texas Gulf Coast in the West Gulf Coastal Plain physiographic province (Fenneman, 1938). The two counties, which have a combined area of 1,562 square miles, are bounded on the north by Liberty and Hardin Counties; on the east by the Neches River, Sabine Lake, and Orange County; on the south by Galveston Bay and the Gulf of Mexico; and on the west by Galveston Bay, Cedar Bayou, and Harris County. Anahuac, the county seat of Chambers County, is 40 miles east of Houston; Beaumont, the county seat of Jefferson County, is 80 miles east of Houston (Figure 1).

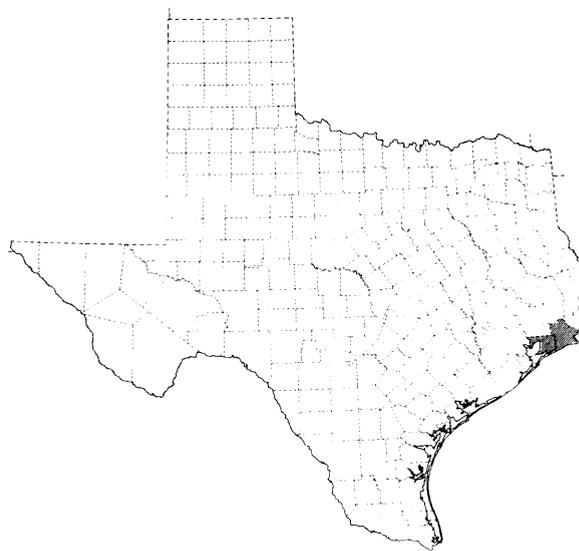

Figure 1.—Location of Chambers and Jefferson Counties

Economic Development

The largest segment of the economy of Chambers and Jefferson Counties is based on the production of petroleum, petrochemicals, natural gas, and sulfur. Since the discovery of oil at Spindletop in 1901, a total of approximately 800 million barrels have been produced in the two counties.

Beaumont and Port Arthur are centers of a petroleum-based industrial complex served by the Intra-coastal Waterway and other canals suitable for ocean-going vessels. Timber, cattle, fresh and salt-water fish, and agricultural products are other important elements of the economy.

In 1965, Chambers and Jefferson Counties had estimated populations of 11,100 and 268,000, respectively. Anahuac, the largest town in Chambers County, had a 1965 population of 2,200; Beaumont, the largest city in Jefferson County, had a 1965 population of 127,800.

Climate

Chambers and Jefferson Counties have a warm humid climate. Precipitation, which averages about 54 inches annually, is well distributed throughout the year but is greatest from May to September.

The average annual temperature at Beaumont is about 21°C (70°F). Temperatures below freezing occur on the average of only 12 days per year, and temperatures about 38°C (100°F) are unusual. The approximate dates of the first and last killing frosts are December 2 and March 2. The average annual precipitation, average monthly temperature, and average monthly precipitation at Beaumont for the period of record beginning in 1931 are shown in Figure 2.

Gross lake-surface evaporation averaged about 47 inches annually for the period 1940 to 1965 (Kane, 1967).

Physiography and Drainage

Chambers and Jefferson Counties are on the extreme seaward margin of the West Gulf Coastal Plain physiographic province and entirely within the Grassland Coastal Prairie Region of Texas (Walker and Miers, 1957). The physiography is of three general types: (1) flat to gently rolling upland, which includes most of the area; (2) the valleys of the Trinity and Neches Rivers; and (3) the coastal border. Altitudes range from sea level to a maximum of 81 feet above sea level at Mont Belvieu (Barbers Hill salt dome) in western Chambers County.

Along a line from Smith Point to Beaumont, a series of remnants of abandoned beaches and beach ridges reach altitudes ranging from 15 to 25 feet. The more prominent of these sandy remnants are about 5 feet above the upland surface. Salt domes form two prominent hills on the upland surface: Barbers Hill, in northwestern Chambers County, about 40 feet above the general land surface and Big Hill, in southwestern Jefferson County, about 20 feet high.

The major streams in Chambers County are the Trinity River, which drains the northwestern part of the county and flows into Trinity Bay near Anahuac; Cedar Bayou, which forms the western boundary of the county and flows into Galveston Bay; Double Bayou, which drains the central part of the county and flows into Trinity Bay south of Anahuac; and Oyster Bayou, Onion Bayou, and East Bay Bayou, which drain the eastern part of the county and flow into East Bay.

The major streams in Jefferson County are the Neches River, which drains the eastern part of the county and flows into Sabine Lake; Pine Island Bayou, which forms the northern boundary of the county and flows into the Neches River; Taylor Bayou and its

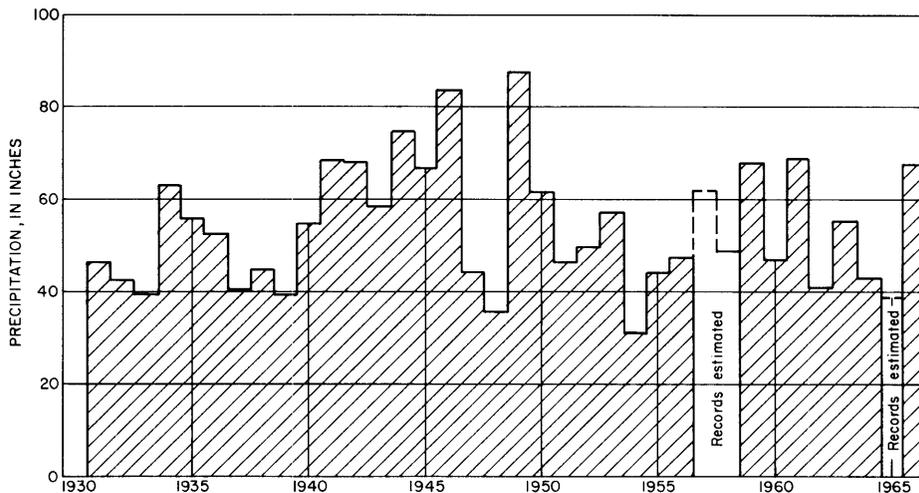

principal tributaries, Hillebrandt and Big Hill Bayous, which drain the western part of the county and flow into Sabine Lake south of Port Arthur; and Spindletop and Salt Bayous, which drain the southern part of the county and flow into the Intracoastal Waterway.

Urbanization and rice cultivation have resulted in the canalization of many streams and the construction of ditches and canals for drainage and irrigation. In some places, natural drainage directions have been changed by deepening parts of the streams.

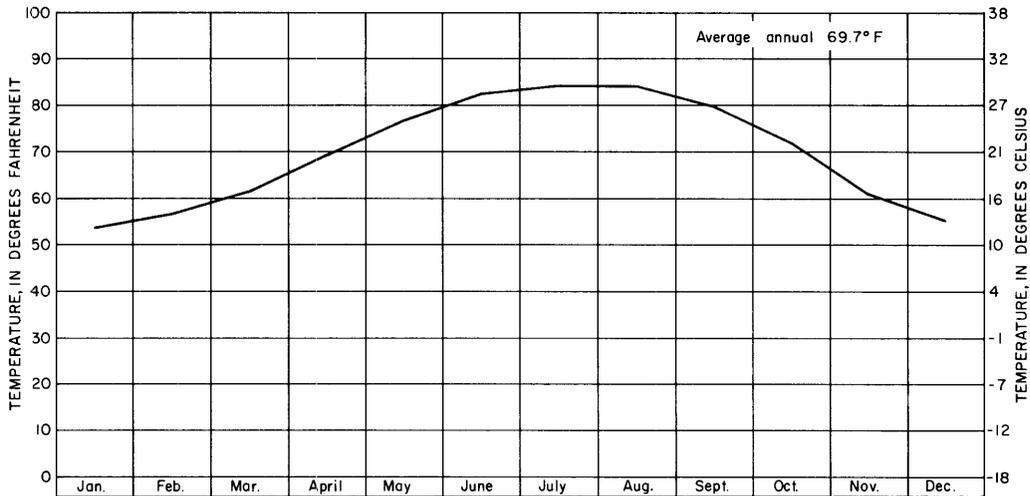

Methods of Investigation

The following items were included in the investigation of the ground-water resources of Chambers and Jefferson Counties:

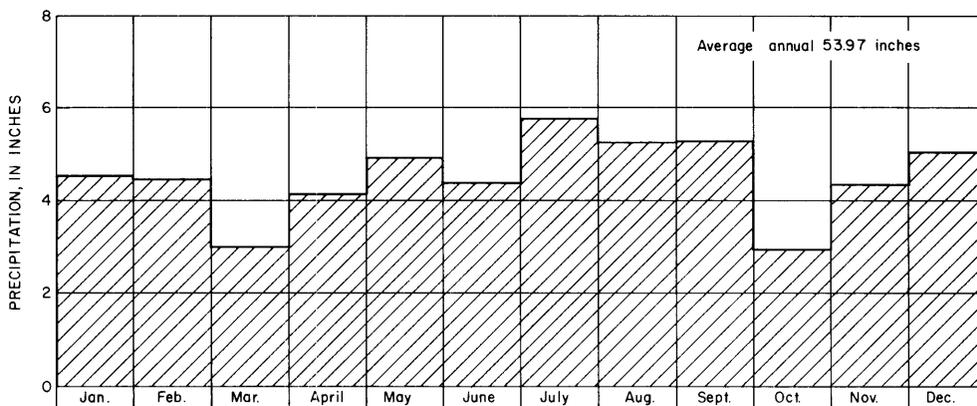

1. An inventory was made of all industrial, public supply, and irrigation wells, and of a representative number of domestic and livestock wells (Table 4). Locations of the wells are shown on Figure 24.
2. Electrical logs and drillers' logs of water wells and oil tests were used for construction of the hydrologic sections (Figures 25 through 28) and for determination of the total thickness of sands containing fresh water (Figures 17 and 18).
3. An inventory was made of the withdrawal of ground water for public supply, irrigation, and industrial use.
4. Pumping tests were made to determine the hydraulic characteristics of the water-bearing sands (Table 2).
5. Altitudes of water wells were determined from topographic maps.
6. Measurements of water levels were made in wells, and available records of past fluctuations of water levels were compiled (Table 6 and Figures 8 through 11).
7. Climatological records were collected and compiled (Figure 2).
8. Analyses of water samples were made to determine the chemical quality of the water (Table 7).
9. Maps, sections, and graphs were prepared to correlate and illustrate geologic and hydrologic data.
10. The hydrologic data were analyzed to determine the quantity and quality of ground water available for development.
11. Data were compiled on the subsidence of the land surface (Figure 12).

12. Problems related to the development and protection of ground-water supplies were studied.

Previous Investigations

Taylor (1907) included wells in Chambers and Jefferson Counties in his report on the underground waters of the Coastal Plain of Texas. Duessen (1914), in a reconnaissance report on the underground waters of the southeastern part of the Texas Coastal Plain, discussed the ground-water geology of Chambers and Jefferson Counties and included a list of wells and springs and drillers' logs of wells.

Livingston and Cromack (1942) inventoried wells in Chambers and Jefferson Counties in 1941 and 1942, and Doyel (1956) published an updated report on Chambers County. Much of the data in these reports was used in this investigation.

Reports by Wood (1956), and Wood, Gabrysch, and Marvin (1963) discussed the ground-water supplies available from the principal water-bearing formations in the Gulf Coast region of Texas, including Chambers and Jefferson Counties.

Water levels have been measured and water samples collected systematically since 1949 in the western part of Chambers County as part of a continuing ground-water program in Harris and Galveston Counties.

Periodic measurements of water levels in wells in Chambers and Jefferson Counties have been made since 1949 as part of the statewide observation-well program in Texas. Records of these measurements are published periodically by the Texas Water Development Board, and records of selected wells in Chambers and Jefferson Counties are published by the U.S. Geological Survey in reports on water levels and artesian pressures in the United States (Hackett, 1962).

Well-Numbering System

The well-numbering system used in this report is the system adopted by the Texas Water Development Board for use throughout the State. Under this system, each 1-degree quadrangle in the State is given a number consisting of two digits. These are the first two digits in the well number. The 1-degree quadrangles are divided into 7½-minute quadrangles which are given two-digit numbers from 01 to 64. These are the third and fourth digits of the well number. Each 7½-minute quadrangle is subdivided into 2½-minute quadrangles and given a single digit number from 1 to 9. This is the fifth digit of the well number. Each well within a 2½-minute quadrangle is given a two-digit number as it is inventoried, starting with 01. These are the last two digits of the well number.

Only the last three digits are shown on the well-location map (Figure 24). The second two digits are generally shown in the northwest corner of each 7½-minute quadrangle, and the first two digits are shown by the large double-lined numbers.

In addition to the 7-digit well number, a two-letter prefix is used to identify the county. Prefixes for Chambers, Jefferson, and adjacent counties are as follows:

COUNTY	PREFIX	COUNTY	PREFIX
Chambers	DH	Hardin	LH
Jefferson	PT	Liberty	SB
Orange	UJ	Harris	LJ

Thus, well DH-64-11-802 (which supplies water for the city of Anahuac) is in Chambers County (DH), in the 1-degree quadrangle 64, in the 7½-minute quadrangle 11, in the 2½-minute quadrangle 8, and was the 2nd well (02) inventoried in that 2½-minute quadrangle.

Acknowledgments

The author acknowledges the assistance of the many county, municipal, and industrial officials who aided in this project. Particular appreciation is expressed to Jett Hankamer and to personnel of Humble Oil and Refining Co., Mobil Oil Corp., Pure Oil Co., Placid Oil Co., Gulf States Utilities Co., Diamond Alkali Co., Warren Petroleum Corp., and Chambers County Water Control and Improvement District No. 1 for permitting and assisting in pumping tests in wells. The Houston Lighting and Power Co. furnished information as it was collected in their testing program east of Baytown.

Well drillers supplied drillers' logs, electrical logs, and well-completion data; and all landowners contacted granted access to their property, wells, and records.

Dr. Saul Aronow, Department of Geology, Lamar State College of Technology, prepared the section of the report on Quaternary geology and aided the author in the task of relating geology to hydrology.

HYDROLOGIC AND GEOLOGIC UNITS

The geologic units composing the aquifers in Chambers and Jefferson Counties are, from oldest to youngest: the Fleming Formation of Miocene age; the Goliad Sand of Pliocene age; the Willis Sand of Pliocene(?) age; the Bentley Formation, Montgomery Formation, and Beaumont Clay of Pleistocene age; the Deweyville deposits of Bernard (1950) of Pleistocene(?) age; and the alluvial, deltaic, coastal marsh, mudflat, and

beach (chenier) deposits of Holocene age. The correlation of geologic and hydrologic units is shown in Table 1.

The Beaumont Clay and the Holocene deposits (described in the section on Quaternary geology) crop out within the two counties. Their surface relationships are shown on the geologic map (Figure 20). The older formations crop out in the counties to the north.

The geologic units are generally composed of sand, silt, and clay, with lesser amounts of gravel, marl, and lignite. Faults are common, especially in the vicinity of salt domes, but surface traces of the fault zones are rarely discernible. Some, but not all, of the salt domes are marked by surface features such as higher altitudes, topographic depressions, or a combination of both.

Figures 25, 26, 27 and 28 are hydrologic sections showing the aquifers, their stratigraphic relationship, and the salinity of the water they contain.

Burkeville Aquiclude

The Burkeville aquiclude, the lowermost hydrologic unit discussed in this report, is principally a clay section within the Fleming Formation and is equivalent, at least in part, to the Castor Creek Member (Fisk, 1940) of the Fleming Formation of Kennedy (1892), as mapped by Rogers and Calandro (1965) in Vernon Parish, Louisiana. The Burkeville is also equivalent to "Zone 2" of Lang, Winslow, and White (1950) in the Houston district.

The Burkeville ranges in thickness from 130 to 300 feet. The unit contains minor amounts of sand in some places but is not a source of water in Chambers and Jefferson Counties. The significance of the Burkeville in the two counties is that it forms the lower confining layer for the overlying Evangeline aquifer.

Evangeline Aquifer

The Evangeline aquifer is the lowermost unit containing fresh or slightly saline water in Chambers and Jefferson Counties. The Evangeline overlies the Burkeville aquiclude and includes the Goliad Sand and sands in the upper part of the Fleming Formation. The aquifer is equivalent to the "heavily pumped" layer of Wood and Gabrysch (1965) in the Houston district. In Louisiana, the unit is equivalent to the Blounts Creek Member (Fisk, 1940) of the Fleming Formation of Kennedy (1892) in Vernon Parish (Rogers and Calandro, 1965) and the Foley Formation in Calcasieu Parish (Harder, 1960).

The Evangeline is about 1,400 feet thick in northern Jefferson County and increases in thickness toward the Gulf. The aquifer yields fresh water to large wells in northwestern Chambers County.

Chicot Aquifer

The Chicot aquifer includes all deposits above the Evangeline aquifer. The unit consists of the Willis Sand, the Bentley Formation, the Montgomery Formation, the Beaumont Clay, the Deweyville Deposits of Bernard (1950), and the Holocene alluvium.

The physical basis for separation of the Evangeline and Chicot is the difference in lithology and permeability. In some areas, the two aquifers are separated by beds of clay, but such beds are not continuous. The units differ in average grain size, cementation, and compaction. The higher permeabilities are usually associated with the Chicot.

The differences noted may be recognized in ways other than by examination of the sediments. A displacement of the spontaneous-potential curve of an electrical log as the logging tool passes out of the Evangeline into the Chicot often marks the contact between the two lithologically dissimilar aquifers. In addition, the formation factor (ratio between aquifer resistivity and aquifer water resistivity) for the two aquifers is generally significantly different. The formation factor for the Chicot aquifer is usually greater. In some areas, where lithologic differences are not pronounced or where changes in water quality makes comparative readings difficult or impossible, the contact between the two aquifers is not readily apparent from electrical logs.

In parts of eastern Jefferson County and western Chambers County, the Chicot aquifer is divided into two units by a clay bed that separates an upper sand section from a lower sand section. There are significant differences in water levels in wells completed in the upper and lower units of the Chicot in eastern Jefferson County and western Chambers County. These sands merge in some places, and in other places, one of the sands may be absent.

In some parts of the two counties, the upper and lower units of the Chicot merge into one large mass of interbedded and interconnected sand and clay as much as 1,600 feet thick. In these areas, determination of a boundary between the two units becomes impossible. This is especially true near some of the shallow piercement-type salt domes and in a large area in central Chambers County. The configuration of the base of the Chicot aquifer and the locations of most of the salt domes in the area are shown on Figure 3.

Lower Unit

In the downdip (southeast) parts of Chambers and Jefferson Counties, the lower unit of the Chicot aquifer is generally two or more massive sands separated by clay. These sands are probably equivalent to the "500-foot" and "700-foot" sands as mapped in Calcasieu Parish, Louisiana (Harder, 1960). In reports on Galveston and Harris Counties, the massive sands of the lower Chicot

unit have been mapped as the Alta Loma Sand of Rose (1943). In Orange County (Wesselman, 1965), the sands were mapped together as the "middle" aquifer.

In much of the updip (northwest) parts of Chambers and Jefferson Counties, the lower unit of the Chicot thins and loses much of the sand that is present downdip. Much of this loss is due to wedging of the unit, but some of the loss is due to facies changes.

Upper Unit

The upper unit of the Chicot consists of a basal sand overlain by clay. Most of the sand is part of the Montgomery Formation and can be traced into the outcrop of this geologic unit. The uppermost overlying clay is Beaumont, but in many places clay of the Montgomery Formation is also present.

No criteria other than the mapping of terrace levels have been developed for separating the Beaumont sands or sands of Holocene age from the underlying sands of the Montgomery Formation. The basal sand of the upper unit of the Chicot may be correlated with the "200-foot" sand of Calcasieu Parish, Louisiana (Harder, 1960).

SOURCE AND OCCURRENCE OF GROUND WATER

The principal source of fresh ground water in Chambers and Jefferson Counties is precipitation. Most precipitation runs off and becomes streamflow or evaporates immediately. Only a small fraction of the rainfall infiltrates to the zone of saturation. The zone of saturation is the zone below the water table where the interstices in the rocks are filled with water. Much of the penetrating water is rapidly returned to the atmosphere by evaporation or transpiration. A large percentage of the water that reaches the zone of saturation in the aquifers is rapidly returned to the surface as spring flow, which supports the base flow of the streams of the area.

Ground water occurs in aquifers. An aquifer is a geologic formation, group of formations, or part of a formation that is water bearing. An aquiclude is an impermeable or relatively impermeable bed that may contain water but is incapable of transmitting an appreciable quantity.

The water in an aquifer exists under one of two conditions, water table or artesian. Under water-table conditions, the water contained in the aquifer is under atmospheric pressure only. The water table is free to rise or fall in response to changes in the volume of water stored. A well penetrating an aquifer under water-table conditions fills with water to the level of the water table.

Artesian conditions occur when an aquifer is overlain by sediments of lower permeability that confine the water under hydrostatic pressure. Such conditions occur downdip from the outcrops of the aquifers. A well penetrating sands under artesian head (pressure) becomes filled with water to a level above the top of the aquifer. If the head (pressure) is great enough to raise the water to a level higher than the top of the well, the water flows. The height above the aquifer that the water will rise in a well is equivalent to the pressure head in the aquifer.

The water in the aquifers moves under the influence of gravity from areas of recharge to areas of discharge. The average velocity of movement is slow, less than a foot a day, except in the immediate vicinity of large wells or springs.

Discharge of ground water occurs both naturally and artificially. Natural means of discharge include evapotranspiration, spring flow, and upward seepage through clays. Artificial discharge is accomplished by pumping from wells; by pumping from excavations that intersect the water table; or by drainage that results when ditches are cut into and below the water table.

RECHARGE, MOVEMENT, AND DISCHARGE OF GROUND WATER

Before man began developing ground water in the Gulf Coast regions, the deeper aquifers had a higher head than the more shallow ones. The original higher piezometric head on the deeper aquifer systems was caused by the outcrops of the deeper aquifers being topographically higher. Downdip from the outcrops, movement of water was generally southeastward, in the direction of the hydraulic gradients, toward areas of natural discharge.

In much of the area, continuous clay beds confined the water, and the only avenue of discharge was upward through the clays. However, in some areas of low altitude, the aquifer sands are not overlain by clay, and fresh water was discharged through the sands. One such area is located between Smiths Point and Monroe City, 6 miles east of Anahuac, in Chambers County and another in the Pine Island Bayou and Neches River lowlands north and east of Beaumont. Much of the artesian fresh water that entered from surrounding counties was discharged as spring flow or seepage in these and similar areas.

The interconnection of the aquifers along the sides of the shallow piercement-type salt domes also provide avenues of discharge. Interconnection is indicated by electric logs and by water-quality data in the vicinity of Barbers Hill, Lost Lake, Moss Bluff, Fannett, Big Hill, and Spindletop Domes (Figure 3).

Originally, fresh and saline waters moved toward these domes under sufficient artesian heads to cause water to flow above land surface. Much of this water was, or became, salty as it passed adjacent to the domes from the lower aquifers to the upper aquifers. Interconnection of the aquifers allowed this deeper and usually more saline water with its higher piezometric head to rise and mix with the fresher water in the upper aquifers. A generalized illustration showing ground-water movement near domes was published by Hanna (1958, p. 11). It is reproduced here as Figure 4.

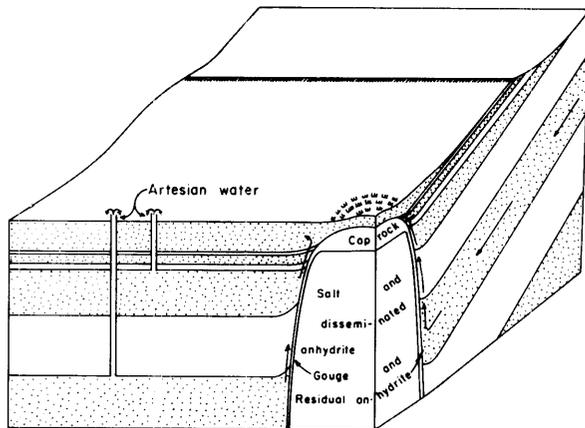

Figure 4.—Idealized Block Diagram Illustrating Ground-Water Circulation Around Salt Domes

Since the development of the ground-water resources of this region began in the 1800's, the subsurface circulation of the water has been changed repeatedly, and new recharge-discharge relationships have been established. Because of ground-water development, water levels declined. Cones of depression around each well altered the natural flow pattern, and water now moves from all directions into these centers of pumping. Withdrawals from the aquifers in Harris and Orange Counties have established large regional cones of depression that extend into Chambers and Jefferson Counties. A smaller cone of depression has been established by pumping in the Winnie-Hamshire area.

The cones of depression have lowered the piezometric surface below land surface in the artesian aquifers at all observed points, and below sea level in much of the area. Because of this alteration, the previously described areas of discharge have, or will soon become, areas of recharge to the underlying aquifers.

Specifically, some parts of the upper unit of the Chicot aquifer in Chambers and Jefferson Counties which formerly discharged water as springs and seeps are probably now recharged with fresh water through these outcrops of sand within the counties. Probably most of the lower unit of the Chicot and the Evangeline aquifers

are still recharged through outcrops in adjoining or nearby counties.

HYDRAULIC CHARACTERISTICS OF THE AQUIFERS

"The worth of an aquifer as a fully developed source of water depends largely on two inherent characteristics: its ability to store and its ability to transmit water" (Ferris and others, 1962, p. 70). These characteristics are measured by the coefficients of storage and transmissibility.

The coefficient of storage is important in any calculation of the quantity of water that can be obtained from an aquifer; but the availability of the water, especially in an artesian aquifer, depends primarily on the ability of the aquifer to transmit water. The coefficient of permeability is a measure of that ability and is defined as the rate of flow of water in gallons per day through a cross-sectional area of 1 square foot under a unit-hydraulic gradient (1 foot per foot) at a temperature of 16°C (60°F). In field practice the adjustment to the standard temperature of 16°C (60°F) is commonly disregarded, and the permeability is then understood to be a field coefficient at the prevailing water temperature. The coefficient of transmissibility is the product of the field coefficient of permeability and the saturated thickness of the aquifer.

The specific capacity of a well is its yield per unit drawdown and can be theoretically related to transmissibility. It is expressed in gallons per minute per foot of drawdown. The measured specific capacity may differ from the computed theoretical specific capacity of a well for one or more reasons. Improper well construction and development, screen losses, unfavorable local geologic conditions, screening only part of the available aquifer—all are factors that will decrease the measured specific capacity. On the other hand, in some wells the effective diameter of the well may be increased by proper development. As a result, the measured specific capacity can be larger than the theoretical. Wood and others (1963, p. 40), referring to the Gulf Coast region, reported that "... the measured specific capacities of most wells in the region are smaller than the theoretical, indicating that many of the sands in the gravel-packed zone are poorly connected to the interior of the screen so that screen losses are considerable during pumping."

The coefficients of storage and transmissibility of the aquifers were determined by aquifer tests made in wells in Chambers and Jefferson Counties. The test data were analyzed by the Theis non-equilibrium method as modified by Cooper and Jacob (1946, p. 526-534), or by the Theis recovery method (Wenzel, 1942, p. 95-97). The results of the tests and specific capacities of the wells are shown in Table 2. None of the wells are completed in a full section of an aquifer, therefore the

values in the table are less than the aquifer's total capability.

The coefficients of transmissibility and storage may be used to predict drawdowns in water levels caused by pumping. The theoretical relation between drawdown and distance from the center of pumping for different coefficients of transmissibility is shown on Figure 5. The calculations of drawdown are based on a withdrawal of 1 mgd (million gallons per day) for 1 year from an aquifer having coefficients of transmissibility and storage as shown and assuming the aquifer has infinite areal extent. For example, if the coefficients of transmissibility and storage are 50,000 gpd (gallons per day) per foot and 0.001, respectively, the drawdown or decline in the water level would be 12 feet at a distance of 1 mile from a well or group of wells discharging 1 mgd for 1 year. If the coefficients of transmissibility and storage are 5,000 gpd per foot and 0.0001, respectively, the same pumping rate for the same time would cause 84 feet of decline at the same distance.

Figure 6 shows the relation of drawdown to distance and time as a result of pumping from an artesian aquifer with characteristics similar to those found in the artesian aquifers of Chambers and Jefferson Counties. To prepare these curves, it was assumed that the aquifers had infinite areal extent. This illustration shows that the rate of drawdown decreases with time. For example, the drawdown at 100 feet from a well is 11 feet after 1 mgd has been pumped for 1 year, and the drawdown is about 15 feet after 1 mgd has been pumped for 100 years. The total drawdown at any one place within the cone of depression (or influence) of several wells would be the sum of the influences of the several wells. The equilibrium curve illustrates the time-drawdown relation when a line source of recharge is 25 miles from the point of discharge.

Figure 7 shows the relation of drawdown to distance and time as a result of pumping from a water-table aquifer with characteristics similar to small parts of the upper unit of the Chicot aquifer. Again, infinite areal extent of the aquifer is assumed. The drawdown is less than that in an artesian aquifer because, under water-table conditions, the coefficient of storage is larger.

Interference between wells may cause a decrease in yield of the wells, or an increase in pumping costs, or both. If the pumping level declines below the top of the aquifer screened, the saturated thickness of the aquifer decreases and the result is a decrease in the yield of the well.

Aquifer tests were run on 10 wells tapping the lower unit of the Chicot aquifer in Chambers and Jefferson Counties. Coefficients of transmissibility ranged from 5,200 to 401,000 gpd per foot and coefficients of permeability ranged from 108 to 1,670 gpd per square foot. The highest permeability was

determined from a test of a saline-water well completed in the lowermost massive sand in the lower unit of the Chicot. Specific capacities ranged from 3.4 to 32.5 gpm (gallons per minute) per foot. The coefficient of storage in the lower unit of the Chicot ranged from 0.0004 to 0.0037.

Tests of 9 wells completed in the upper unit of the Chicot showed the following ranges in coefficients: transmissibilities from 10,800 to 29,800 gpd per foot; permeabilities from 174 to 596 gpd per square foot; and specific capacities from 1.7 to 11 gpm per foot. Two determinations of the coefficient of storage were 0.0007 and 0.0002.

Tests were made in two wells completed in the Evangeline aquifer. The coefficients of transmissibility were 32,000 and 36,000 gpd per foot and coefficients of permeability were 244 and 327 gpd per square foot. The coefficient of storage was 0.00003. The specific capacity of one of the wells was 16.2 gpm per foot. These results compare favorably with those observed in nearby areas. Tests of the "heavily pumped layer" (Evangeline aquifer) in the Houston district show the average coefficient of permeability to be about 250 gpd per square foot, and tests in Jasper and Newton Counties northeast of the report area showed an average of 260 gpd per square foot.

PRODUCTION AND USE OF GROUND WATER

The first production of ground water in Chambers and Jefferson Counties was probably from holes dug into beach ridges by Indians who hunted and fished along the Gulf Coast. Early permanent settlers of the region utilized mostly shallow wells. Deussen (1914) reported many deep, fairly large wells, most of which flowed. These wells had been drilled in the decades preceding and following 1900. Oil exploration together with the development of rice irrigation in southeastern Texas and southern Louisiana caused many wells to be drilled. The extent and quality of the ground water were fairly well known at that time.

Penn Livingston and G. H. Cromack (written commun., 1943) reported that in Jefferson County, production of ground water, stimulated by oil field development, irrigation, and the construction of refineries, rose to a peak of about 25 mgd in 1926. Much of this development was in areas underlain mostly by slightly or moderately saline water. The poor quality of much of the water probably discouraged its use as production decreased to about 10 mgd in 1927. In 1941, the combined production in Chambers and Jefferson Counties was probably a little less than 8.5 mgd. Total production of ground water in both counties decreased to about 5 mgd in 1948. Development of the upper unit of the Chicot aquifer in the Winnie-Hamshire, Anahuac, and Hankamer areas; of the Evangeline and Chicot

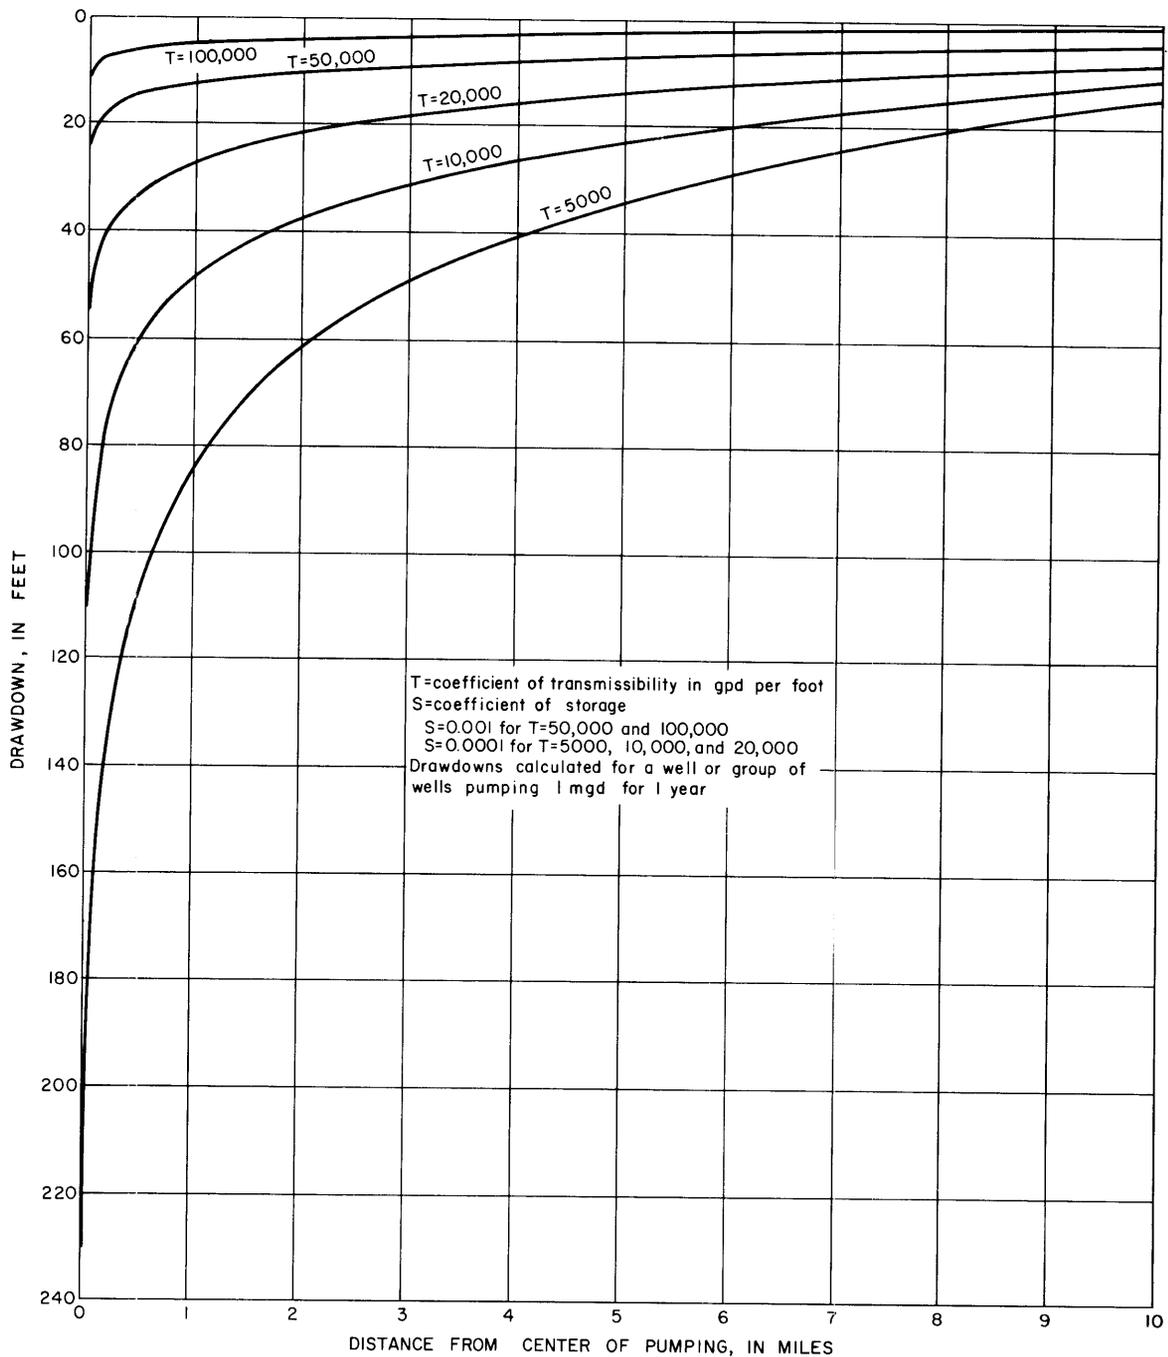

Figure 5.—Relation of Drawdown to Transmissibility and Distance

aquifers in the Mont Belvieu-Baytown area; and of the lower Chicot in the Beaumont-Port Arthur area raised the production rate to 8.6 mgd by 1965.

Most of the ground water developed prior to World War II was taken from the lower unit of the Chicot aquifer in the Beaumont-Port Arthur area, whereas production in 1965 was divided about equally among the upper unit of the Chicot, lower unit of the Chicot, and the Evangeline. The principal areas of

production are the Mont Belvieu-Baytown area of western Chambers County, the Winnie-Hamshire area of Chambers and Jefferson Counties, and the Beaumont-Port Arthur area of Jefferson County. Other sites where significant ground-water withdrawals occur include the Big Hill Dome, the flank of High Island Dome, Redfish Reef in Galveston Bay, Hankamer, and Anahuac. The locations of wells in Chambers and Jefferson Counties and adjacent areas are shown on Figure 24.

* Permeability based on screen length.

The production of water from wells in Chambers and Jefferson Counties in 1965 was as follows (figures are in mgd):

COUNTY	CLASS OF USE			TOTAL *
	INDUS-TRIAL	MUNICIPAL	IRRIGA-TION	
Jefferson	3.1	1.0	.5	4.6
Chambers	2.0	1.0	1.0	4.0
Total *	5.1	2.0	1.5	8.6

* Figures are approximate because some of the production was estimated.

About 30 percent of this production (about 2.5 mgd) was slightly or moderately saline water used by industry.

The high salinity of much of the ground water has restricted its use. Consequently, the primary sources of water have been the Neches and Trinity Rivers, and most of the needs of industry, irrigation, and large municipalities in the area from the mid-1920's until the 1950's were met from these sources. However, the consistent quality and uniform temperature of ground water was especially desirable for some uses and as early as the 1920's, ground water produced from the lower unit of the Chicot aquifer in Orange County was imported by a refinery in the Port Arthur area.

The total estimated use of ground water (including imported ground water) in Chambers and Jefferson Counties in 1965 was approximately 18.6 mgd. Of this, 10 mgd was fresh water produced from wells in Hardin and Orange Counties and imported by the city of Beaumont and industries in Beaumont and Port Arthur. In 1958, Beaumont started supplementing its surface-water supply with ground water from a well field tapping the Evangeline aquifer in Hardin County, and in 1965 obtained 6 mgd from this field. According to Underwood Hill, Water Superintendent of Beaumont (personal commun., July 8, 1967), the city of Beaumont plans to expand its usage of ground water to 20 mgd by 1980.

Two industries in Beaumont and Port Arthur in 1965 imported 4 mgd of ground water produced from the lower unit of the Chicot aquifer in Orange County. One industry in Port Arthur has been importing about 0.5 mgd since the 1920's. The other developed its supply in 1962.

Because sufficient quantities of fresh ground water are not available locally and large supplies of fresh

ground water are available nearby, further importation of fresh ground water from outside the counties is probable.

WATER LEVELS

Water-level data are presented by hydrographs and maps. Data gathered during the 1941-42 inventory and during inventories since 1942 were used in the preparation of Figures 8 and 9. Water-level measurements are presented in Tables 4 and 6.

Long-term records of water levels indicate the magnitude of the water-level changes that have occurred in the Chicot aquifer. Measurements show that in well PT-64-06-401 (Figure 9), the differences in the high and low water levels were less than 2 feet during the period of record 1941-66. The largest change in water levels occurred in the lower unit of the Chicot aquifer in western Chambers County in the area adjacent to the city of Baytown, where water levels dropped more than 90 feet during the period 1941-66. The 1966 measurements, compared with the early reports of flowing wells, indicate that water levels have declined at least 150 feet. No long-term water-level records are available for the Evangeline aquifer. Water levels have possibly declined as much in the Mont Belvieu area as the decline recorded in the lower unit of the Chicot in the Baytown area.

Evangeline Aquifer

Water-level measurements in wells completed in the Evangeline aquifer in Chambers and Jefferson Counties date back only a few years. The levels that have been measured are in the Mont Belvieu area, and these closely approximate the levels in the lower Chicot in the same area.

Chicot Aquifer

The water levels and other criteria used to separate the upper and lower units of the Chicot aquifer in most of Chambers and Jefferson Counties were not sufficient to separate the two units in a large area centered near the eastern edge of Trinity Bay in Chambers County. Inspection of the maps (Figures 10 and 11) and of the hydrographs of wells (Figure 9) shows that the declines and seasonal fluctuations of water levels have been less in this area than in the areas to the east and west of it.

Lower Unit

The map of the 1941 and 1966 water levels in the lower unit of the Chicot aquifer (Figure 10) shows large depressions in western Chambers County as early as

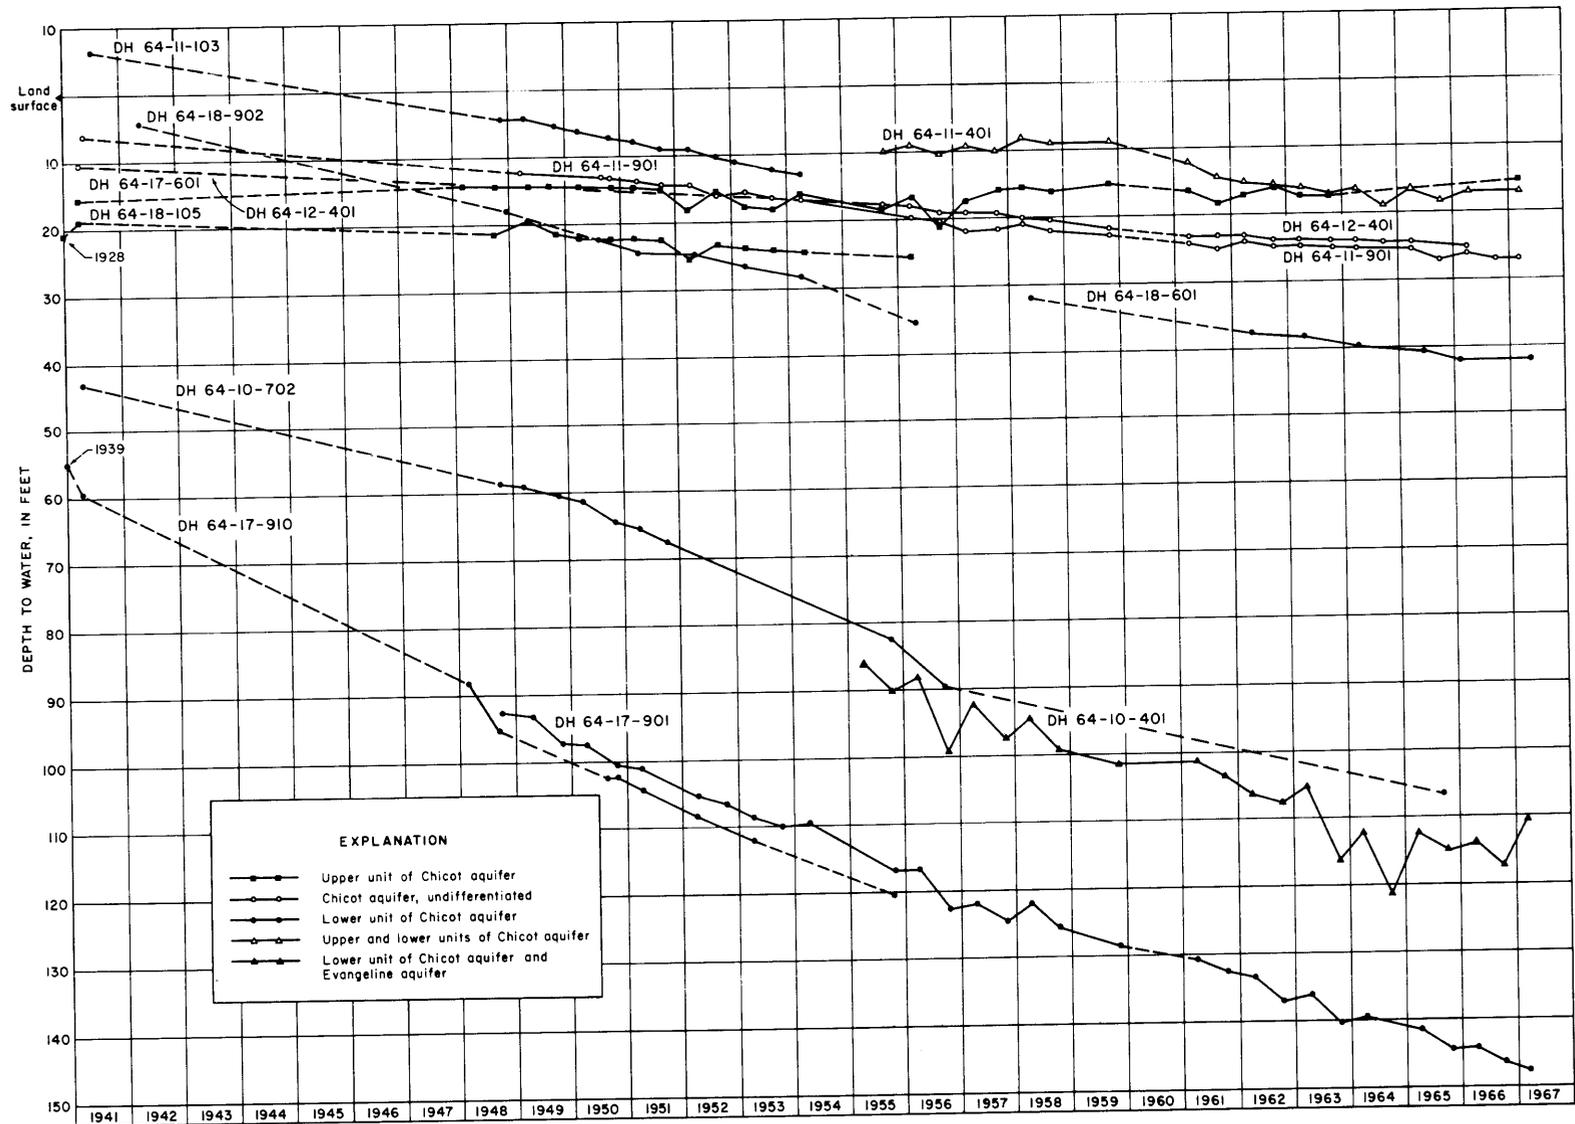

Figure 8
Changes in Water Levels in Wells Tapping Various Aquifers in Chambers County

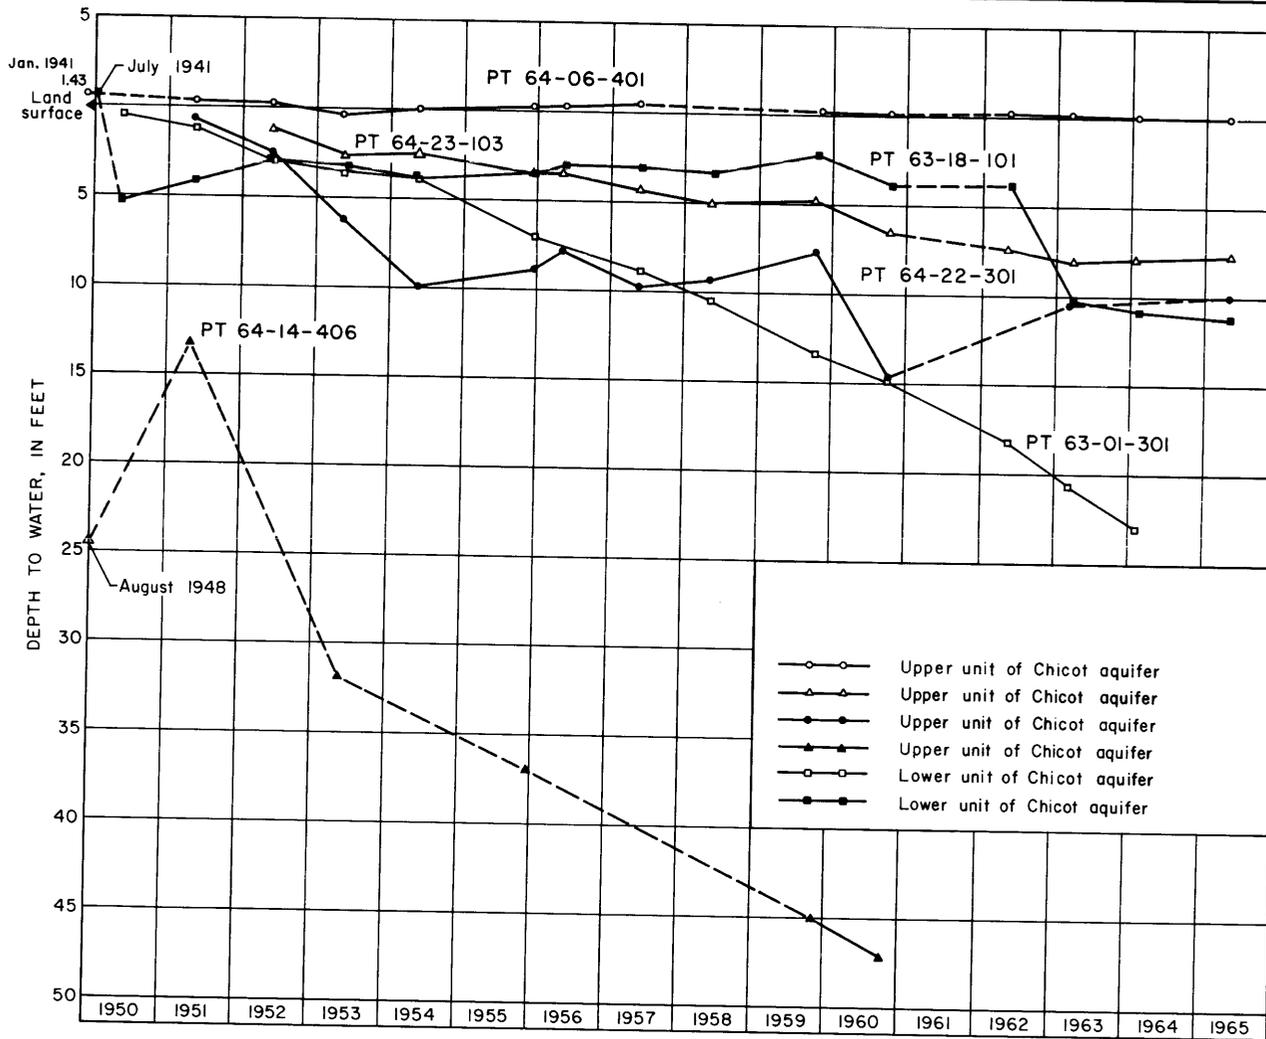

Figure 9
 Changes in Water Levels in Wells Tapping the Upper
 and Lower Units of the Chicot Aquifer in Jefferson County

1941. These depressions were caused by heavy pumping in Galveston and Harris Counties. Contour lines on the map indicate that water in the lower unit of the Chicot aquifer was moving from western Chambers County into Harris and Galveston Counties in 1941. The direction of movement in 1966, as indicated by the map, is still the same, but the hydraulic gradient and the rate of movement have increased.

The effect of pumping from the lower Chicot in the Beaumont-Port Arthur-Orange area of eastern Jefferson and southern Orange Counties before 1941 is reflected in the shape of the contours. By 1966, the pumping center of this area was well defined. Pumping by chemical industries, municipalities, and from irrigation wells in Orange County caused a regional cone of depression that is reflected by the contours (Figure 10). The cone of depression extends into eastern Jefferson County, consequently, the movement of the water in this area is from Jefferson County into Orange County.

Upper Unit

The map of water levels in the upper unit of the Chicot aquifer in 1941 and 1966 (Figure 11) does not indicate any large regional centers of withdrawals in 1941. However, pumping depressed the water surface below sea level in areas a few miles west of Port Arthur and near Groves in Jefferson County and in the vicinity of Houston Point and Wallisville in Chambers County.

By 1966, the industrial, municipal, and irrigation withdrawals in the vicinity of Winnie had created a cone of depression (Figure 11) in eastern Chambers and western Jefferson Counties.

RELATION OF WATER-LEVEL DECLINES TO LAND-SURFACE SUBSIDENCE

The withdrawal of water from an artesian aquifer results in an immediate decrease in hydraulic pressure which partially supports the weight of the overlying rocks. With reduction in pressure, an additional load is transferred to the skeleton of the aquifer and a pressure difference between the sands and clays causes water to move from the clays to the sands. The entire process results in compaction of the sediments, most of which takes place in the clays. Because of the compaction, the land surface subsides.

Regional subsidence in the Texas Gulf Coast is due principally to the extraction of water, although subsidence may also occur because of the removal of oil and gas. In addition to other factors, the amount of

decline in artesian head and the thickness of clay are important to total subsidence. R. K. Gabrysch (oral commun., 1967) found that in the Houston district, which includes the western part of Chambers County, subsidence ranged from 0.5 foot to 1.5 feet for each 100 feet of artesian head decline. The ratio of 0.5 foot subsidence per 100 feet head decline occurred in an area where the section contained about 40 percent clay. As the clay percentage increased, the ratio of subsidence to head decline increased. In the area of 1.5 feet subsidence per 100 feet head decline, clay composed about 70 percent of the section.

Winslow and Wood (1959) show that lowering of the artesian head by development of ground water has resulted in subsidence of the land surface in most of the upper Gulf Coast region of Texas. They mapped the extent of this subsidence by comparing measurements of bench-mark altitudes made at different times by the U.S. Coast and Geodetic Survey. Their map shows that the land surface subsided more than 0.5 foot in western Chambers County between 1918 and 1954. For this period of time, their map showed less than 0.25 foot subsidence for most of the rest of Chambers and Jefferson Counties. A small area in eastern Jefferson County had subsided more than 0.25 foot and an extremely local area, in the vicinity of the Spindletop Dome, subsided more than 1 foot. The areas that subsided, with the exception of the Spindletop Dome, are areas in which artesian head has declined. Subsidence at Spindletop is related to the production of oil. Extremely localized subsidence sometimes takes place when sulfur is removed from the cap rock of the salt domes by the Frasch process. A depression over 15 feet deep, which is periodically enlarging and deepening, is present at the Moss Bluff Dome on the Liberty-Chambers County line just east of the Trinity River. The Frasch process of removing sulfur has been initiated at the Fannett and Spindletop Domes in the last decade but noticeable subsidence that could be attributed to this cause was not found during this study.

The latest releveing of bench marks by the U.S. Coast and Geodetic Survey was in 1964, but only a part of the area mapped by Winslow and Wood was releveled. Gabrysch (1967) showed that subsidence in the western part of Chambers County has continued. Figure 12, a contour map of subsidence in the Houston district, shows that a maximum of 2 feet of subsidence occurred at the eastern edge of the city of Baytown (along the western edge of Chambers County) during the period 1943-1964. East of the area shown on Figure 12, regional subsidence through 1967 probably has been mostly less than 0.5 foot. In small areas, such as Lost Lake, Moss Bluff (north of Lost Lake), Hankamer, High Island, Big Hill (8 miles southeast), and Fannett, subsidence due to the removal of oil and gas probably is greater than 0.5 foot.

Figure 12
 Subsidence of Land Surface in the Houston District, 1943-64

A sufficient number of bench marks, necessary to determine subsidence in detail, is not available in much of Chambers and Jefferson Counties.

WELL CONSTRUCTION

Generally, when a well is to be constructed for public supply or industrial use in a new location, a test hole is drilled to the depth desired. Formation samples are collected during drilling, and after completion of the test hole, an electrical log is run. The log is used to determine the occurrence of sands and to indicate in general the quality of water they contain. Some of these test holes are used to collect water samples for chemical analysis and to measure the water-yielding properties of the sands.

If favorable ground-water conditions are indicated by the data collected, the test hole is usually reamed to the top of the first sand that is to be screened; surface casing is then installed and cemented into place. The diameter of the surface casing in most large-capacity wells in Chambers and Jefferson Counties ranges from 12 to 20 inches.

The section to be screened is then reamed with the largest drilling bit that can pass through the surface casing. The hole is then underreamed by a device that expands and cuts a hole larger than the diameter of the surface casing, usually to a diameter of 30 inches. Blank pipe and screen are then installed with part of the blank pipe extending up into the surface casing. The bottom of the screen is closed off with a back-pressure valve that permits the use of fluid to keep the hole clean during emplacement of the screen, but prevents water, sand, or gravel from entering through the bottom. Gravel or sand is then pumped into the annular space between the screen and the well bore. The gravel reservoir—the space between the bottom of the surface casing and the top of the blank pipe—is also filled with gravel. The construction of a typical industrial or public-supply well is shown on Figure 13.

Usually the screen is steel pipe, 6 to 14 inches in diameter, that has been perforated and wrapped with stainless steel wire. Where corrosion is a problem, the pipe may be stainless steel. Generally the openings in the screen, which are as much as 0.05 inch wide, are larger than the sand particles in the formation but smaller than those of the gravel envelope. Blank pipe of the same diameter as the screen is used to separate screens and is positioned opposite clay beds in the producing intervals.

The well may be developed by surging, swabbing, pumping, back-washing, and by chemical treatment until the specific capacity of the well indicates complete development and the sand-water ratio is satisfactory. The final production test usually lasts from 4 to 24 hours, during which samples of water for chemical and bacterial analyses are collected.

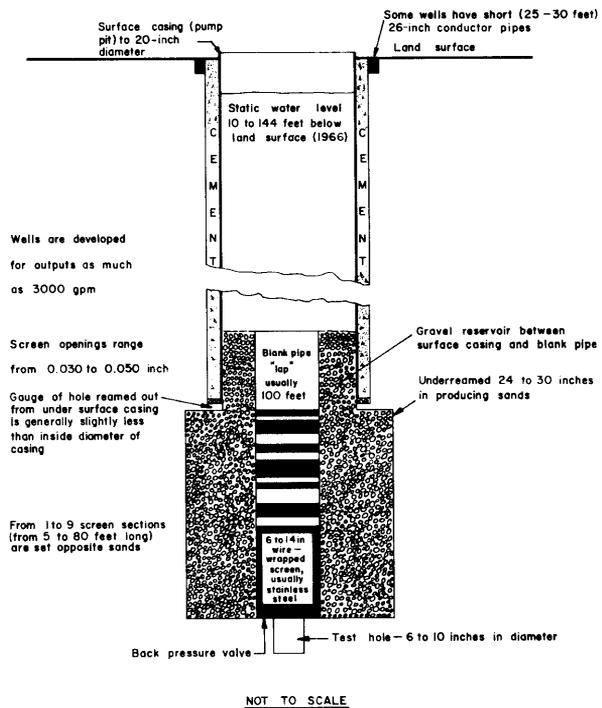

Figure 13.—Construction of Industrial and Public Supply Wells

Some large irrigation wells have been constructed in a similar manner, with slotted pipe being used instead of wrapped screen. More commonly, however, a large diameter hole is drilled from the surface to the finished depth, no cement is used, and gravel is placed outside the entire casing string. In some smaller diameter irrigation wells, screen is selected to fit the sands encountered, and no gravel is used.

The size and type of pump installed on the large-capacity wells depend upon the pumping lift and the quantity of water needed. The larger public-supply and industrial wells have high-capacity, deep-well turbine pumps powered by electricity. Irrigation wells are equipped with the same type of pumps but are powered by diesel or gas motors.

Although shallow dug wells, usually 30 to 36 inches in diameter, have been constructed in a few localities, most of the modern, small-capacity wells used for domestic or industrial supply are drilled wells that have been completed with a single screen.

A variety of screen types are available. Stainless steel and plastic have become the most widely used in Chambers and Jefferson Counties because of their resistance to corrosion. Plastic is coming into widespread use as the material for conductor pipe and screens in the small and relatively shallow wells. Stainless steel screen is used in the large wells.

Oil-rig drill pipe is used as casing in most of the water-supply wells drilled in the oil fields of Trinity Bay. Because of its thick walls, the time it takes the pipe to corrode and the well to fail is extended.

Various types of pumps are used on small-capacity wells. New small wells are usually equipped with submersible pumps, whereas older wells, particularly those in areas of lowered artesian head, are usually equipped with the deep jet-type pumps. Windmills in conjunction with cylinder-type pumps are still used to lift water for livestock use, particularly in remote locations, but many windmills are being replaced by electric-powered pumps.

QUALITY OF GROUND WATER

The chemical constituents of ground water originate principally from the soil and rocks through which the water has moved. Table 3 lists many of the chemical constituents and properties of water and discusses their source and significance. The chemical analyses of water from selected wells in Chambers and Jefferson Counties are given in Table 7.

The quality of water commonly determines its suitability for use. A general classification of water, according to dissolved-solids content in mg/l (milligrams per liter), is as follows (modified from Winslow and Kister, 1956, p. 5):

DESCRIPTION	DISSOLVED-SOLIDS CONTENT (MG/L)
Fresh	Less than 1,000
Slightly saline	1,000 to 3,000
Moderately saline	3,000 to 10,000
Very saline	10,000 to 35,000
Brine	More than 35,000

Maps showing the base of fresh water, the base of slightly saline water, and the thickness of sands containing fresh water are included in this report as Figures 16, 17, 18, and 19. Analysis of these maps and the cross sections (Figures 25 through 28) shows that most of the water underlying Chambers and Jefferson Counties is slightly or more than slightly saline.

Suitability for Public Supply

The U.S. Public Health Service (1962, p. 7) has established standards for the chemical quality of water to be used on common carriers engaged in interstate commerce. These standards, which are commonly used in evaluating public water supplies, are included in Table 3.

According to the U.S. Public Health Service (1962, p. 41), the optimum fluoride level for a given community depends on climatic conditions, because the amount of water (and consequently the amount of fluoride) ingested is influenced primarily by air temperature. In Chambers and Jefferson Counties, the optimum concentration based on the annual average of maximum daily air temperature of 26.1°C (79°F) at Beaumont is 0.8 mg/l. Presence of fluoride in average concentrations greater than twice the optimum value, or 1.6 mg/l, would constitute grounds for rejection of the supply. Excessive concentrations of fluoride are present in the water from some wells in Chambers and Jefferson Counties.

The 1941-42 well inventory and water-sampling program (Livingston and Cromack, 1942a, 1942b) included analyses of water from shallow wells (9 to 47 feet deep) in the upper unit of the Chicot aquifer that showed more than the recommended limit (45 mg/l) of nitrate concentration. However, the nitrate concentration in water from all deeper wells sampled at that time was less than the recommended limit. Samples from only a few shallow wells were collected in 1966. Of these, only one well (PT-64-08-403), 27 feet deep, yielded water with an excessive amount of nitrate. Also, the deeper wells sampled in 1966 did not have excessive nitrates. The presence of nitrates in excess of the limit in the shallow wells suggests pollution by sewage or by other organic material.

Water having a chloride content exceeding 250 mg/l may have a salty taste, and sulfate in water in excess of 250 mg/l may produce a laxative effect. Much of the water produced in Chambers and Jefferson Counties has a chloride content greater than 250 mg/l. Excessive amounts of sulfates occur in water in some shallow sands and in some of the deeper sands near the shallow salt domes.

About half of the samples analyzed for iron showed that this constituent was present in excess of the 0.3 mg/l limit. A relationship between iron concentration and depth of the well was not established, and it was not determined whether the iron occurred naturally or as a product of interaction between the water and the metal parts of the well.

Suitability for Industrial Use

The suitability of water for industrial use is dependent upon the process in which the water is used. Water for cooling and boiler uses should be noncorrosive and relatively free of scale-forming constituents, of which hardness and silica are the most important.

The silica content (Table 7) in water from the aquifers in these counties ranged from 5.3 to 38 mg/l. Moore (1940, p. 263) suggested the following allowable concentration of silica in boilers operating at various

Table 3.--Source and Significance of Dissolved-Mineral Constituents and Properties of Water

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE
Silica (SiO ₂)	Dissolved from practically all rocks and soils, commonly less than 30 mg/l. High concentrations, as much as 100 mg/l, generally occur in highly alkaline waters.	Forms hard scale in pipes and boilers. Carried over in steam of high pressure boilers to form deposits on blades of turbines. Inhibits deterioration of zeolite-type water softeners.
Iron (Fe)	Dissolved from practically all rocks and soils. May also be derived from iron pipes, pumps, and other equipment. More than 1 or 2 mg/l of iron in surface waters generally indicates acid wastes from mine drainage or other sources.	On exposure to air, iron in ground water oxidizes to reddish-brown precipitate. More than about 0.3 mg/l stains laundry and utensils reddish-brown. Objectionable for food processing, textile processing, beverages, ice manufacture, brewing, and other processes. U.S. Public Health Service (1962) drinking-water standards state that iron should not exceed 0.3 mg/l. Larger quantities cause unpleasant taste and favor growth of iron bacteria.
Calcium (Ca) and magnesium (Mg)	Dissolved from practically all soils and rocks, but especially from limestone, dolomite, and gypsum. Calcium and magnesium are found in large quantities in some brines. Magnesium is present in large quantities in sea water.	Cause most of the hardness and scale-forming properties of water; soap consuming (see hardness). Waters low in calcium and magnesium desired in electroplating, tanning, dyeing, and in textile manufacturing.
Sodium (Na) and potassium (K)	Dissolved from practically all rocks and soils. Found also in ancient brines, sea water, industrial brines, and sewage.	Large amounts, in combination with chloride, give a salty taste. Moderate quantities have little effect on the usefulness of water for most purposes. Sodium salts may cause foaming in steam boilers and a high sodium content may limit the use of water for irrigation.
Bicarbonate (HCO ₃) and carbonate (CO ₃)	Action of carbon dioxide in water on carbonate rocks such as limestone and dolomite.	Bicarbonate and carbonate produce alkalinity. Bicarbonates of calcium and magnesium decompose in steam boilers and hot water facilities to form scale and release corrosive carbon dioxide gas. In combination with calcium and magnesium, cause carbonate hardness.
Sulfate (SO ₄)	Dissolved from rocks and soils containing gypsum, iron sulfides, and other sulfur compounds. Commonly present in mine waters and in some industrial wastes.	Sulfate in water containing calcium forms hard scale in steam boilers. In large amounts, sulfate in combination with other ions gives bitter taste to water. Some calcium sulfate is considered beneficial in the brewing process. U.S. Public Health Service (1962) drinking-water standards recommend that the sulfate content should not exceed 250 mg/l.
Chloride (Cl)	Dissolved from rocks and soils. Present in sewage and found in large amounts in ancient brines, sea water, and industrial brines.	In large amounts in combination with sodium, gives salty taste to drinking water. In large quantities, increases the corrosiveness of water. U.S. Public Health Service (1962) drinking-water standards recommend that the chloride content should not exceed 250 mg/l.
Fluoride (F)	Dissolved in small to minute quantities from most rocks and soils. Added to many waters by fluoridation of municipal supplies.	Fluoride in drinking water reduces the incidence of tooth decay when the water is consumed during the period of enamel calcification. However, it may cause mottling of the teeth, depending on the concentration of fluoride, the age of the child, amount of drinking water consumed, and susceptibility of the individual. (Maier, 1950)
Nitrate (NO ₃)	Decaying organic matter, sewage, fertilizers, and nitrates in soil.	Concentration much greater than the local average may suggest pollution. U.S. Public Health Service (1962) drinking-water standards suggest a limit of 45 mg/l. Waters of high nitrate content have been reported to be the cause of methemoglobinemia (an often fatal disease in infants) and therefore should not be used in infant feeding. Nitrate has been shown to be helpful in reducing inter-crystalline cracking of boiler steel. It encourages growth of algae and other organisms which produce undesirable tastes and odors.
Dissolved solids	Chiefly mineral constituents dissolved from rocks and soils. Includes some water of crystallization.	U.S. Public Health Service (1962) drinking-water standards recommend that waters containing more than 500 mg/l dissolved solids not be used if other less mineralized supplies are available. Waters containing more than 1000 mg/l dissolved solids are unsuitable for many purposes.
Hardness as CaCO ₃	In most waters nearly all the hardness is due to calcium and magnesium. All the metallic cations other than the alkali metals also cause hardness.	Consumes soap before a lather will form. Deposits soap curd on bathtubs. Hard water forms scale in boilers, water heaters, and pipes. Hardness equivalent to the bicarbonate and carbonate is called carbonate hardness. Any hardness in excess of this is called non-carbonate hardness. Waters of hardness as much as 60 ppm are considered soft; 61 to 120 mg/l, moderately hard; 121 to 180 mg/l, hard; more than 180 mg/l, very hard.
Specific conductance (micromhos at 25°C)	Mineral content of the water.	Indicates degree of mineralization. Specific conductance is a measure of the capacity of the water to conduct an electric current. Varies with concentration and degree of ionization of the constituents.
Hydrogen ion concentration (pH)	Acids, acid-generating salts, and free carbon dioxide lower the pH. Carbonates, bicarbonates, hydroxides, and phosphates, silicates, and borates raise the pH.	A pH of 7.0 indicates neutrality of a solution. Values higher than 7.0 denote increasing alkalinity; values lower than 7.0 indicate increasing acidity. pH is a measure of the activity of the hydrogen ions. Corrosiveness of water generally increases with decreasing pH. However, excessively alkaline waters may also attack metals.

pressures: less than 150 psi (pounds per square inch), 40 mg/l; 150-250 psi, 20 mg/l; 250-400 psi, 5 mg/l; and more than 400 psi, 1 mg/l.

A classification commonly used with reference to hardness is as follows: 60 mg/l or less, soft; 61 to 120 mg/l, moderately hard; 121 to 180 mg/l, hard; and more than 180 mg/l, very hard. If water used in steam boilers has more than 75 mg/l hardness as calcium carbonate, it should be treated to prevent the formation of scale (American Society for Testing Materials, 1959, p. 24). In high-pressure boilers, the tolerance is much less than 75 mg/l. Suggested water-quality tolerances for a number of industries are summarized by Hem (1959, p. 253) from Moore (1940). Although the hardness of the water (Table 7) ranges from soft to very hard, most of the water sampled was moderately hard or hard.

Large amounts of water are used to dissolve salt from salt domes to create caverns for storage of gas; the quality of water used for this purpose is not important. In some chemical processes, water of uniform chemical quality, clarity, and temperature is necessary, and even slightly or moderately saline ground water often meets these conditions better than surface water. In water-flooding operations, saline ground water is often preferred because of its compatibility with fluids in the formation and because it is usually organically pure and sediment-free.

The temperature of water is often of great importance to industry and to other users. The temperature of ground water near the land surface is approximately the same as the mean annual air temperature of the region, 20.9°C (69.7°F) at Beaumont, but increases with depth. The lowest temperature of ground water recorded during the study, from a well 159 feet deep, was 22°C (71°F). The highest water temperature recorded during the study, from a well 1,255 feet deep, was 29.2°C (84.6°F). Temperature of ground water at any particular depth remains relatively constant throughout the year.

Suitability for Irrigation

The suitability of water for irrigation depends on the chemical quality of the water and on other factors such as soil texture and composition, types of crops, irrigation practices, and climate. The most important chemical characteristics pertinent to the evaluation of water for irrigation are: the proportion of sodium to total cations—an index of the sodium hazard; total concentration of soluble salts—an index of the salinity hazard; RSC (residual sodium carbonate); and the concentration of boron.

A system of classification commonly used for judging the quality of water for irrigation was proposed by the U.S. Salinity Laboratory Staff (1954, p. 69-82). This classification is based primarily on the salinity

hazard as measured by the electrical conductivity of the water and on the sodium hazard as measured by the SAR (sodium-adsorption ratio). Although this classification was used in Figure 14, it may not be directly applicable because of the high rainfall. Wilcox (1955, p. 15-16) stated that water would be safe for supplemental irrigation if its conductivity was less than 2,250 micromhos per centimeter at 25°C and if its SAR was less than 14. This classification does show that in Chambers and Jefferson Counties most water tested had a high to very high salinity hazard and a low to very high sodium hazard. However, of the 62 water samples represented on the diagram, 30 samples were within the safe limits for supplemental irrigation. Most of these samples were taken from the freshest portions of the aquifers and the 32 samples which showed the water to be probably unsafe for even supplemental irrigation are probably most representative of most of the water in the aquifers of Chambers and Jefferson Counties.

An excessive concentration of boron renders a water unsuitable for irrigation. Scofield (1936, p. 286) indicated that boron concentrations of as much as 1 mg/l are permissible for irrigating most boron-sensitive crops and that concentrations of as much as 3 mg/l are permissible for the more boron-tolerant crops. All but one analysis (Table 7) which list boron show a concentration less than 1 mg/l.

Another factor in assessing the quality of water for irrigation is the RSC of the water. Excessive RSC will cause water to be alkaline, and the alkaline water will cause organic material of the soil to dissolve. The affected soil, which may become grayish-black, is referred to as "black alkali". Wilcox (1955, p. 11) states that laboratory and field studies have resulted in the conclusion that water containing more than 2.5 me/l (milliequivalents per liter) RSC is not suitable for irrigation. Water containing from 1.25 to 2.5 me/l is marginal, and water containing less than 1.25 me/l RSC is probably safe. Correct irrigation practices and proper use of amendments to the soil might make possible the successful use of marginal water for irrigation. In the majority of the samples analyzed, the RSC was high, the maximum value being 9.31 me/l.

The high conductivity (salinity hazard) and the generally unfavorable SAR and RSC values shown in the analyses are probably among the factors responsible for the abandoning of numerous irrigation wells in Chambers and Jefferson Counties in the past.

RELATIONSHIP OF FRESH GROUND WATER TO SALINE GROUND WATER

Two distinct relationships between fresh and saline water are evident in the Chicot and Evangeline aquifers in Chambers and Jefferson Counties. The normal relationship is for the fresh water to float on the salt water because of the greater density of the latter. This

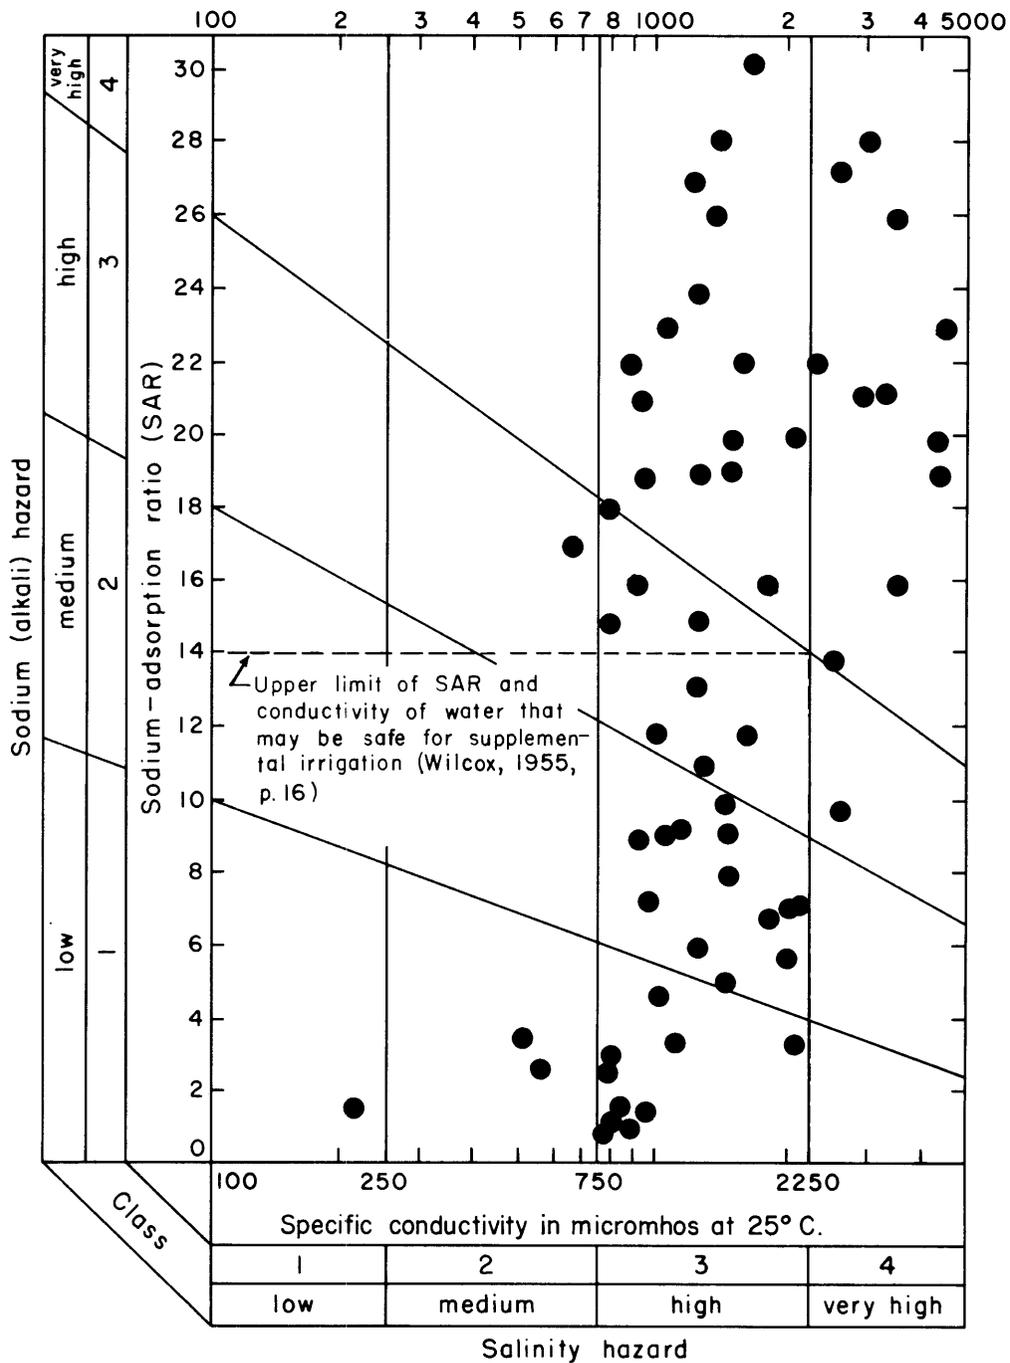

Figure 14
Classification of Irrigation Waters

relationship is modified by the interbedding of sands and clays. Fresh water occurs at depths greater than 1,400 feet under these conditions in Chambers and Jefferson Counties.

The other relationship occurs in the vicinity of the salt domes. The domes are composed of about 90 to 95 percent rock salt and 5 to 10 percent impurities, most of which is anhydrite (Hanna, 1958, p. 7). These domes have penetrated the sands and clays and placed soluble salt in contact with the water in the aquifers.

Originally, the shallowest and most permeable aquifer, the Chicot, had the lowest artesian head. Saline water has entered the lower beds of the Chicot aquifer near the domes that penetrate it. Saline water has also deteriorated the quality of the water in the Evangeline aquifer, near these domes.

When water dissolved the salt near the top and along the sides of the domes, much of the impurities in the salt remained as residue. Most of this residue was left at the top of the domes, where it became the parent material for the cap rock. Portions of this anhydrite have been altered to gypsum, lime, and sulfur. The high sulfate concentrations found in the analysis of some water from the Chicot in the vicinity of the domes probably originates from processes taking place in the cap rock.

Figure 4, a block diagram and hydrologic section showing the relationship of the ground water and its quality to the Barber's Hill Dome at Mont Belvieu, indicates that the poorer quality water in the lower unit of the Chicot aquifer can be traced from the dome to the northeastern edge of Baytown (6 miles away). Electric logs indicate that a similar relationship exists in the Nome area of Jefferson County, south of the Sour Lake Dome in Hardin County.

Sands that crop out north of the Fannett Dome, in the vicinity of the town of Fannett, contain only saline water even at very shallow depths. Because the area is topographically higher than the surrounding area, these sands should contain fresh water. The presence of saline water is probably a result of deeper artesian saline water flowing upward around the periphery of the dome and discharging into the shallower sands. Before well development, surface springs or seeps probably discharged some of this water.

DISPOSAL OF OIL-FIELD BRINES AND OTHER CONTAMINANTS

According to a 1961 salt-water inventory, about 60.4 million barrels of oil-field brine was produced during 1961 in Chambers and Jefferson Counties. Of this quantity, 66 percent was returned to saline water-bearing formations by injection wells, 26 percent was released to surface-water courses, 7.5 percent was

disposed of in open pits, and 0.5 percent was disposed of by miscellaneous or "unknown" processes (Texas Water Commission and Texas Water Pollution Control Board, 1963, p. 46-86 and 258-287).

The method of disposal of least danger to fresh ground-water supplies is injection through properly constructed wells; probably the most dangerous method is disposal of the brine in open pits. In Chambers and Jefferson Counties, the average annual precipitation is 54 inches and the average annual gross lake-surface evaporation is 47 inches. To be effective in brine disposal, the open pit must be constructed in sandy soil. Such construction allows the brine to seep into the ground, thereby contaminating the ground water. Most open pits are constructed in clay soil and act as holding or storage ponds. They may fill and overflow to the nearest stream or area of sandy soil.

Although contamination of ground water has probably occurred in places from the disposal of oil-field brines, no known large-scale damage to the ground-water supplies of Chambers and Jefferson Counties has occurred. Dead trees and other vegetation noted in the vicinity of old brine pits were probably killed by brine that overflowed or seeped out of the pits. In most of these areas, injection wells have replaced pits. Many injection wells have been drilled since the 1961 salt-water inventory, and the ratio of pit to injection-well disposal is constantly improving.

Large quantities of saline waste water are produced by industry in the vicinity of salt domes and large quantities of waste water are released in these and in other industrial areas. Much of this water comes from sulfur mining and from the construction of storage chambers in salt domes. Facilities to gather and hold the waste water exist at most domes. At some locations this water is injected back into the subsurface, but at most locations ditches carry this water to large holding ponds or lakes from which the water is released to the surface-water courses of the area. Controlled releases from these lakes are made so as to minimize the effect on natural waters.

Contamination of the shallow ground water probably takes place in the vicinity of many of the gathering, holding, and release systems that are excavated in the surface formations. Those in clay probably do not need lining, but those systems in sandy soil are probably contributing inferior quality water to an already limited source of fresh ground water.

Most towns and industries dispose of their effluent in the tidal portion of the streams or into the bays, which already contain saline water. The most harmful effect of this practice is that under certain conditions this effluent kills fish and wildlife, and the effluent often imparts noxious odors and colors to the streams and bays.

PROTECTION OF WATER QUALITY IN OIL-FIELD DRILLING OPERATIONS

The Railroad Commission of Texas requires that contractors drilling oil and gas wells use casing and cement to protect fresh-water strata from contamination. For more than the past decade, the Railroad Commission has received recommendations from the Texas Water Development Board and from its predecessors, the Texas Water Commission and the Texas Board of Water Engineers, concerning the depths to which the water should be protected.

Where oil or gas fields are established, the recommended depths are incorporated in some of the field rules. Figure 15 shows the amount of surface casing required by the Oil and Gas Division of the Railroad Commission of Texas and the depth of slightly saline water in those fields in Chambers and Jefferson Counties having surface-casing requirements. Figure 16 is a map showing the approximate altitude of the base of slightly saline water.

of fresh water is stored in northern Jefferson County; however, only a small part of this water could be recovered because of specific retention of much of this water and because of encroachment of nearby salt water. The fresh water extends to depths greater than 1,400 feet below sea level in western Chambers County and to depths of more than 1,000 feet below sea level in northern Jefferson County. Areas where fresh water occurs in the Evangeline aquifer underlie less than 10 percent of the combined areas of these counties. The maximum thicknesses of fresh-water sands is greater than 400 feet in Chambers County and greater than 200 feet in Jefferson County (Figure 17). Several large capacity industrial wells are completed in the Evangeline on the southwest flank of the Barbers Hill Dome. One irrigation well, in the Houston Point area of Chambers County, is completed in the Evangeline and lower unit of the Chicot.

Wells yielding 1,000-3,000 gpm could be constructed in northwestern Chambers County where sands in the Evangeline contain fresh water to depths approaching 1,500 feet below sea level.

AVAILABILITY OF GROUND WATER

Evangeline Aquifer

The Evangeline aquifer contains fresh water only in parts of western Chambers County and northern Jefferson County. Assuming a porosity of 30 percent, about 2,600,000 acre-feet of fresh water is stored in western Chambers County and about 800,000 acre-feet

Some sands of the Evangeline aquifer contain fresh water in parts of the Houston Point area. These sands and the Chicot sands above them are currently being tested and evaluated by the industries that are establishing new plants. Limited uses for sanitary purposes and boiler-feed water are planned. Wells yielding 100-1,000 gpm from the Evangeline aquifer could be developed in this area. The proximity of slightly saline water in the same beds in this area will probably preclude any large scale development of this water as a dependable source.

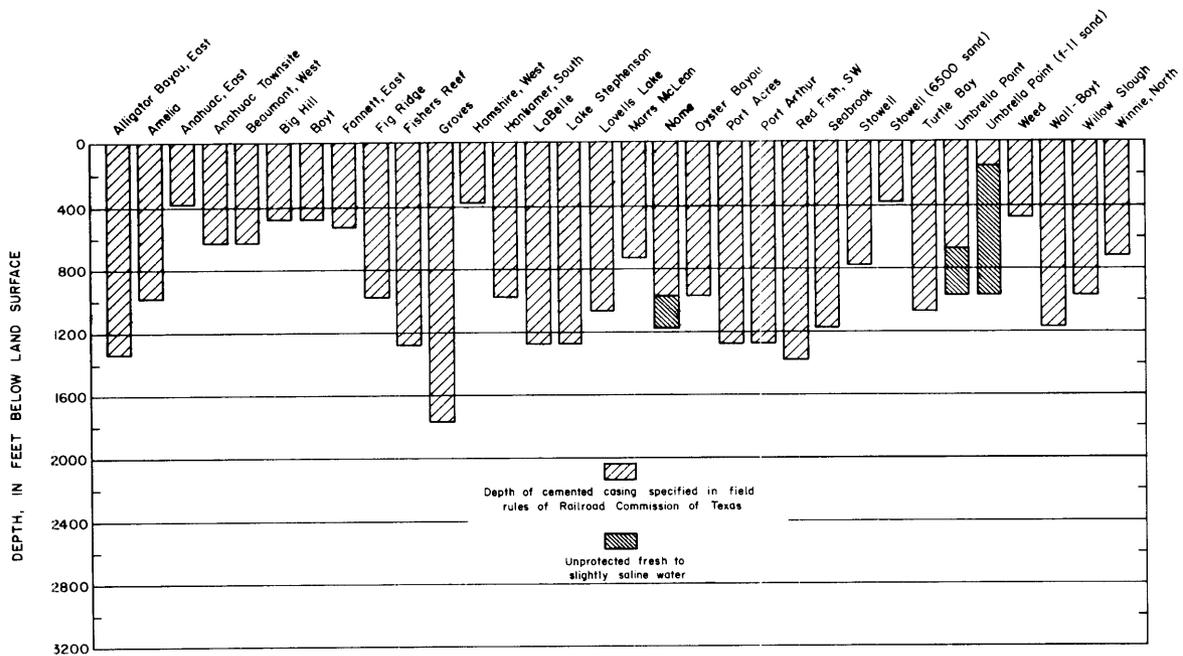

Figure 15.—Comparison Between Surface-Casing Requirements in Oil Fields and Depth of Base of Sands Containing Fresh to Slightly Saline Water

Chicot Aquifer

Lower Unit

The approximate base and thickness of the fresh-water sands in the lower unit of the Chicot aquifer are shown on Figure 18. The lower unit of the Chicot contains fresh water in the Houston Point, Mont Belvieu, and Galveston Bay areas of Chambers County and in a small area along the eastern boundary of Jefferson County. The deepest occurrence of fresh water is in western Chambers County where fresh water extends to depths of more than 800 feet below sea level. Here the net thickness of sands containing fresh water is greater than 100 feet. In Jefferson County the maximum sand thickness is less than 50 feet. Fresh water in this aquifer underlies about a third of Chambers County and less than 5 percent of Jefferson County.

In the Houston Point and Mont Belvieu areas of northwestern Chambers County, the only place in which the lower unit of the Chicot has not been affected by saline water from Barbers Hill Dome is northwest of the dome. In this small area, all of the water in the aquifer is fresh. Large capacity wells that would produce fresh water could be constructed here.

The town of Mont Belvieu is using two public-supply wells (DH-64-09-301 and DH-64-09-302) near the saline water. Water from the public-supply wells will probably become more saline as pumping continues.

Assuming a porosity of 30 percent, almost 4,000,000 acre-feet of fresh water is stored in the lower unit of the Chicot aquifer in Chambers County, 2,900,000 acre-feet of which underlies 150 square miles of Galveston Bay. Only a small part of these quantities could be pumped, however, because of specific retention of much of the water and because of encroachment of nearby salt water.

About 150,000 acre-feet of fresh water is stored in the lower unit of the Chicot aquifer in Jefferson County. The wells tapping this fresh-water supply are all near the interface of the fresh water with the slightly saline water. Extensive development of additional fresh water will cause saline water to move into the wells. Many of the wells developed in this aquifer in eastern Jefferson County already produce slightly or moderately saline water which is used by industry for cooling and fire protection. Wells that produce up to 3,000 gpm have been developed in the aquifer, and additional wells of this capacity can be constructed.

Generally, more than 100 feet of saturated sand containing slightly to moderately saline water is present in most places, and in a large area along the southern boundaries of the counties, massive beds in the aquifer total more than 500 feet in thickness. Large (tens of mgd) sustained withdrawals of moderately saline water

could be made in most areas of the two counties without excessive drawdown in water levels.

Upper Unit

The most widespread aquifer containing fresh water in Chambers and Jefferson Counties is the upper unit of the Chicot. Generally, it contains fresh water in and beyond the same areas as the lower unit of the Chicot and the Evangeline aquifers. However, in over 50 percent of Chambers and Jefferson Counties, only small supplies can be developed in this aquifer. Individual sand beds range in thickness from several feet to about 50 feet. Wells produce or have produced up to 1,000 gpm of fresh water from this aquifer in the Houston Point area of eastern Chambers County, at Anahuac, and in a fairly large area centered at Winnie. Additional fresh-water wells can be constructed in this aquifer in these areas of Chambers County and in extreme northern Jefferson County without an immediate threat of water-quality deterioration.

Throughout much of Chambers and Jefferson Counties water of poorer quality underlies or occurs at short distances from many of the producing wells. With continued pumpage, some of these wells probably will produce poorer quality water.

The approximate altitude of the base of fresh water in the upper unit of the Chicot aquifer is shown in Figure 19. The deepest occurrence of fresh water is in the northernmost part of Jefferson County where the base is greater than 200 feet below sea level. The base of fresh water becomes more shallow to the south and is only a few feet below sea level in the central and southern parts of Chambers and Jefferson Counties.

QUATERNARY GEOLOGY

By

Saul Aronow

Geologic field studies in southeastern Texas that contributed to the preparation of this report were supported by grants from the National Science Foundation, Lamar Tech Research Center, and Sigma Xi.

Most of the systematic field work was done as part of the Geologic Atlas of Texas project of the Bureau of Economic Geology of the University of Texas. The geologic map of Chambers and Jefferson Counties (Figure 20) was adapted from preliminary copies of the Houston and Beaumont sheets of the Geologic Atlas (Bureau of Economic Geology, 1968a and 1968b).

The Soil Conservation Service of the U.S. Department of Agriculture provided technical assistance in the

field and provided copies of published and unpublished maps of soil surveys in Chambers and Jefferson Counties.

Marcus E. Milling, Marcus W. Walsh, Ben Wicker, and George Zahar, geology students at Lamar Tech, aided the author in mapping geomorphic features, in the preparation of illustrations, and in the determination of stream gradients.

General Stratigraphy and Structure

The geologic units in Chambers and Jefferson Counties (Figure 20) crop out in belts that are nearly parallel to the shoreline of the Gulf of Mexico. The beds dip toward the Gulf, with the older beds dipping at steeper angles than the younger beds. Most formations thicken downdip. The regional (gulfward) dip is interrupted by uplifts associated with salt domes and by arcuate belts of normal faults that are generally down-thrown to the Gulf.

The oldest unit that crops out in Chambers and Jefferson Counties is the Beaumont Clay of Pleistocene age (Bernard, LeBlanc, and Major, 1962). The alluvial terrace deposits along the modern floodplains of the Trinity and Neches Rivers, mapped by Bernard (1950) as the "Deweyville beds", are probably of late Pleistocene and Holocene age. The youngest sediments are flood-plain, deltaic, coastal marsh, mud flat, and beach (chenier) deposits of Holocene age.

Beaumont Clay

The Beaumont Clay crops out across most of Chambers and Jefferson Counties (Figure 20). The formation was described by Hayes and Kennedy (1903, p. 27-29), from exposures and from samples from wells in the vicinity of Beaumont, as a "series of yellow, gray, blue, brown, and black clays with black sands" overlying the "Columbia sands."

No definite type section has been described, and probably no complete section can be described from the outcrops alone. A type well or a combination type well and surface section can be established only when some unequivocal means of determining the base of the formation can be agreed upon. Bernard (1950) mapped the Beaumont in Texas as its presumed equivalent in Louisiana, the Prairie Formation; Doering (1956) mapped it as the Oberlin and Eunice Formations; Price (1947) mapped it as the Montgomery and Prairie Formations; and Bernard and LeBlanc (1965) reverted to the original name, Beaumont Clay, as used on the geologic map of Texas (Darton and others, 1937).

Two mappable facies of the Beaumont Clay occur in Chambers and Jefferson Counties: (1) a clayey facies composed of alluvial, deltaic, coastal marsh, and

lagoonal deposits of clay, silty clay, and sandy clay; and (2) a sandy facies composed of barrier island and beach deposits of very fine to fine sand, which are of local importance as sources of small quantities of fresh ground water.

The clayey facies of the Beaumont composes almost all of the exposed Pleistocene sediments in Chambers and Jefferson Counties. For descriptions of these facies see Crout and others (1965), McEwen (1963, p. 63-64), Kunze and others (1963), and Graf (1966, p. 6, and Figure 8).

The sandy facies of the Beaumont Clay compose a very small percentage of the exposed Pleistocene sediments in Chambers and Jefferson Counties. The material is mostly very fine to fine, well-sorted sand of the barrier island and beach deposits (mapped separately on Figure 20). Grain-size determinations by mechanical analyses and heavy-mineral data are given in Graf (1966).

Deltaic and Meander Belt Deposits

Barton (1930a, 1930b) concluded that the coastal area of southeastern Texas was deltaic plain deposited by Pleistocene streams. The main evidence for this interpretation was the meandering pattern of the sandier soils, found in many places on the crests of low "levee" ridges. Barton pointed out that most of the present drainage is between and is controlled by the old levee or distributary ridges.

The major difference between the views of Barton and those of the author is in the significance of the levee or distributary ridges. Barton believed that the meander belts were a relict group of passes with a "palmate" pattern, similar to that of the present-day Mississippi Delta. The deposits of the Pleistocene Trinity River would therefore represent a delta as large as or larger than the present Mississippi Delta. Barton concluded that the Pleistocene Trinity River had a greater discharge and load than at present because of higher precipitation and a diminution in the drainage basin since the Pleistocene. The author believes that this group of passes was actually a succession of meander belts that terminated in relatively small deltas, similar in size to the present day Trinity River Delta.

A map compiled from the latest soil survey of Jefferson County (Crout and others, 1965) that shows the meander belts defined by mapping the soils that are related to fluvial deposits is shown as Figure 21.

As shown in Figure 22, there are four well-preserved, more or less continuous meander belts and one less definite belt in Chambers and Jefferson Counties. In order of decreasing age, they are: (1) the Neches Ridge System, which roughly parallels the Neches River in the extreme eastern part of Jefferson

County—the relict meanders in this system are fragmentary and obscure, but the soils are similar to the soils found in the other systems;(2) the Barbers Hill System, between the Trinity River and Cedar Bayou; (3) the Sea Breeze System, in eastern Chambers County; (4) the Big Hill Ridge System; and (5) the China Ridge System, which is the best preserved and has the greatest continuity.

The system of straight stretches of relict stream channels to the northwest and southeast of the Smith Point and Pine Island barriers may be the remains of a stream that was not a tributary to the Pleistocene Trinity River but flowed directly into the Gulf. Figure 20 shows a number of anomalous meanders that cannot be defined as a coherent system.

The bluffs along Trinity Bay and along the valleys of the Trinity and Neches Rivers are the result of stream cutting during a glacial lowering of sea level. Wave erosion of the areas bordering Lake Anahuac and Trinity Bay has maintained the steepness of the bluffs in those areas. East of the Trinity River, the contact of the Deweyville deposits with the Beaumont Clay is marked by low scarps less than 10 feet in height.

The contact of the Beaumont Clay with the marsh and fluvial deposits of Holocene age between Smith Point in Chambers County and Sabine Lake in Jefferson County has a digitate pattern, and only a few of the recesses are occupied by larger streams. Most of the salients of the Beaumont Clay are levee or distributary ridges similar to those of the Trinity River Delta, and the center lines of some of them are water-filled or marshy depressions. Those that do not have axial depressions can be identified by their sandy soils, by their terminal position in relation to the meander system, and by their areal pattern. The margins of most of these small deltas, which are about 5 feet above sea level, slope gently under the marsh deposits. The termination of the Neches Ridge System does not have a clearly digitate pattern, but does have approximately the same elevation as the other terminations.

The average slope of the surface of the Beaumont Clay east of the Trinity River in Chambers County is about 1 foot per mile. West of the Trinity River, the slope is about 1.5 feet per mile. The gradients of the two best preserved meander belts (not the old stream gradients) are: Big Hill Ridge System, 1.64 feet per mile; and China Ridge System, 0.92 foot per mile. The reconstructed stream gradients are: Big Hill Ridge System, 0.75 foot per mile; and China Ridge System, 0.49 foot per mile.

McEwen (1963), in his study of the most recent delta of the Trinity River, found that the whole delta was only about 15 feet thick. On this basis, a local thickness for the Beaumont Clay of less than 100 feet can easily be conjectured. Should a widespread and easily identifiable lithologic change be found that has

some reasonable relationship to the subsurface projection of the surface of the Montgomery Formation, then perhaps the base of the Beaumont can be defined.

Barrier Island and Beach Deposits

The barrier island and beach deposits (Figure 20) were first described by W. A. Price (1933, 1947), and named for the occurrence at Ingleside, near Aransas Pass, Texas. As mapped by Price, the Ingleside System is a series of discontinuous features extending along most of the Gulf Coast of Texas. In Chambers and Jefferson Counties, the barrier island and beach deposits, which are composed of very fine to fine sand, may be divided into three sections—one in Chambers County and two in Jefferson County (see areas marked Qbb on Figure 20). The section in Chambers County consists mainly of three elongated parts, each less than 1 mile wide, extending from Smith Point northeastwardly for a distance of about 20 miles. The part from Smith Point to Lake Stephenson is a ridge that rises about 10 feet above the adjacent marshland (altitude about 12 feet). The ridge contains a number of small, nearly circular lakes. The remainder of this section is more easily identified on soil maps and aerial photographs. The sections in Jefferson County are west of Fannett and in the western part of the city of Beaumont. The one west of Fannett is an irregularly shaped area about 4 miles in width that is essentially a series of abandoned beaches of “cheniers” similar to those near Sabine Pass. Altitudes range from about 15 to 25 feet. This section is forested and is locally called “Lawhorn Woods.” The section in the western part of the city of Beaumont is about 3 miles long and about 1 mile in width. The altitude is about 20 feet, but because of urban development, this section is difficult to identify.

Mounds and Depressions

Widespread surface features of the Beaumont Clay, and of the Deweyville deposits, are the “pimple mounds.” These circular to elliptical mounds are about 15 to about 50 feet in diameter and 1 to 4 feet in height. They are almost exclusively limited to the sandier and siltier soils that underlie the relict meander belts and the barrier island and beach system. They are largely absent from the gentle swales or relict backswamp areas between meander belts and from some, but not all, of the relict lagoonal areas landward of the old barriers. Pimple mounds are best developed and most abundant on the old barriers.

The origin of pimple mounds is not clearly understood, and they have been considered the result of both organic and inorganic processes. Mounds of this type are not restricted to the Gulf Coast, and similar features elsewhere are sometimes referred to as mima mounds. Discussion of these features goes back to the 1870's; reviews of the literature and references can be

found in Melton (1954), Holland and others (1952), and in Bernard and Leblanc (1965, p. 174-176).

The hog wallows or "gilgai microrelief" (Crout and others, 1965, p. 6; Mowery and others, 1960, p. 11, 33), are a minor but locally conspicuous kind of surface feature. These are areas of uneven or "wavy" ground consisting of very low mounds or microknolls (less than 2 feet in diameter and less than 8 inches in height) and intervening depressions. They usually become apparent after a heavy rain when the depressions impede surface drainage. In Chambers and Jefferson Counties, hog wallows are restricted to the clayier soils. They are thought to result from the unequal absorption of water or dehydration by certain clay minerals.

Geologic Age

The Beaumont Clay is at least 30,000 years old as determined by radiocarbon dating. McFarlan (1961, p. 133) reported that samples from the Prairie Formation of Louisiana (correlative with the Beaumont Clay) were "dead" and older than 30,000 years. Oyster shells collected by the author from the relict lagoonal area north of Lake Charles, Louisiana, were likewise "dead" and were older than 40,000 years according to Dr. E. L. Martin, Shell Development Co., Exploration and Production Research Division, Houston, Texas. The shell material collected near Winnie by Professor W. H. Matthews was also "dead" and older than 37,000 years according to the Humble Oil and Refining Company (now Esso Production Research), Houston, Texas.

Deweyville Deposits of Bernard (1950)

The Deweyville deposits in Chambers and Jefferson Counties are found along the Trinity and Neches Rivers and are intermediate between the Beaumont Clay and the modern flood plain deposits of the two rivers.

These deposits were first mapped and described by H. A. Bernard (1950), in an unpublished doctoral dissertation. They were named for the community of Deweyville, in Newton County, Texas, about 12 miles north of Orange, Texas, where the deposits form a terrace flanking the Holocene flood plain of the Sabine River. On the Beaumont and Houston Sheets of the Geologic Atlas of Texas (Bureau of Economic Geology, 1968a and 1968b), the Deweyville deposits are identified as the Deweyville Formation.

Along the Neches River in Jefferson County, the Deweyville deposits form a single-level terrace north of the city of Beaumont. The deposits range from silty clay to very fine sand in some places and from very fine sand to coarse sand in others. The top of these deposits, which are at least 30 feet thick, is about 20 feet above sea level.

In Chambers County, the Deweyville deposits are on the eastern side of the Trinity River where they form at least three terrace levels ranging in altitude from 15 to 25 feet. As seen in road cuts, the deposits are clayey silts and silty sands. In several sand pits, the clayey silts and silty sands are underlain by very fine to coarse sand. Incomplete soil maps in the office of the U.S. Soil Conservation Service in Anahuac show that the higher terraces are underlain in many places by soils that are characteristic of the Beaumont Clay, and therefore may be considerably older than the deposits along the Neches River where a sequence of terraces is not present.

The age of the Deweyville deposits has been determined by radiocarbon methods for several localities outside of Chambers and Jefferson Counties. Aronow (1967) reported on samples from deposits along the Trinity, San Jacinto, and Sabine Rivers; and B. H. Slaughter (1965) reported on a sample, which the author interprets to be Deweyville, from deposits along the Trinity River. The dates of these samples range from 13,250 to 25,700 years. Bernard and Leblanc (1965, p. 149) give dates ranging from 17,000 to 30,000 years, but no localities are identified in their paper.

Holocene Deposits

Alluvial and Deltaic Deposits

The principal alluvial deposits of Holocene age are along the Neches River in Jefferson County, along the Trinity River in Chambers County, and in an extensive area along the coast. The principal deltaic deposits of Holocene age are at the mouth of the Trinity River. A map by Kane (1959) showing subsurface contours on top of the oxidized Pleistocene deposits (base of the Holocene) in the vicinity of Sabine Lake is included on Figure 23.

The geomorphology of the floodplains and deltas of the Holocene Trinity River has been worked out in some detail by Aten (1966a and 1966b), who distinguishes a sequence of five delta terminations. The sediments and the three-dimensional geometry of the most recent delta have been studied in detail by McEwen (1963), who divides the sediments of the delta into nine facies or genetic groups.

The modern delta of the Trinity began to form within the past 1,000 years. McEwen (1963, p. 93) reports that the two oldest radiocarbon dates of articulated *Rangia flexuosa* shells found in cores taken near the bottom of delta-front churned sands in the northwest part of the delta are 810 years and 750 years old.

Subsurface Contours on Top
of the Oxidized Pleistocene
Deposits in the Vicinity of
Sabine Lake, Texas and Louisiana

(From Kane, 1959)

Coastal Marsh, Mudflat, and Beach (Chenier) Deposits

The coastal marsh, mud flat, and beach (chenier) deposits along the southern margins of Chambers and Jefferson Counties are the most extensive of the Holocene deposits. The coastal marsh sediments underlie the low plains areas separated from the Gulf by the most recent beaches and include the deposits between relict beaches in the Sabine Pass area of Jefferson County (See Bernard and LeBlanc, 1965, Figure 5). The mud flats are the areas of fine-grained sediments gulfward of the most recent beaches.

The surface features in the Sabine Pass area of Texas consist of low beach ridges and intervening relict mud flat or coastal marsh deposits. As can be seen on Figure 20, these arcuate beach ridges or cheniers, convex towards the present shoreline, merge to the southwest into a single beach along the present coast. The ridges, which are 3 to 8 feet in height and as much as 10 miles long, consist of very fine to fine sand with a highly variable shell content. The sand is similar in size to the Holocene beach sands of Galveston Island and Bolivar Peninsula to the west and to the cheniers in Louisiana to the east. (See Hsu, 1960, p. 381-384; Garner, 1967, p. 49-52, 57).

A number of wells, all less than 15 feet deep, have been developed in the beach and associated shell deposits.

Arcuate, fan-like arrangement of the beach ridges on the Texas side of Sabine Pass is more or less duplicated on the Louisiana side of the Pass. This arrangement undoubtedly indicates the gradual closing of the mouth of Sabine Lake by constriction of its southern connection with the Gulf. Originally, Sabine Lake must have been an open estuary of the Gulf. Kane (1959) in his study of the micro-fauna and sediments of Sabine Lake concludes that the micro-fauna, especially the foraminifers, found in the sediments beneath the lake "are similar to those of the present Gulf, indicating greater circulation of saline waters from the Gulf of Mexico before the south end of Sabine Lake was restricted".

Geologic History

The geologic history of the surface formations of Chambers and Jefferson Counties can be tied into the framework of the Pleistocene and Holocene history of the western Gulf Coast region as worked out by H. N. Fisk and his many associates. Later work and areal extensions of Fisk's concepts have been recently and excellently summarized in Bernard and LeBlanc (1965) which contains references to Fisk's many papers.

Fisk believed that the Pleistocene formations of Louisiana and Texas were all deposited as coast-wise

terraces between the major stages of continental glaciations, with each successive Pleistocene formation being tilted gulfward. The amount of tilt was cumulative, so that the oldest formation has a considerably greater dip than the youngest.

The Montgomery Formation (with a regional slope of more than twice that of the Beaumont Clay) was deposited during the Sangamon Interglaciation; the Beaumont Clay, or Prairie Formation, was deposited during post-Sangamonian time. (See Fisk and McFarlan, 1955). The glacial stages were times of low sea level when the streams of the Gulf Coast entrenched their channels well below present-day sea level. Estimates of the lowering of sea level during the last glacial stage range from about 300 to 450 feet. The Trinity and Neches Rivers, during the last lowering of sea level, flowed over a 100-mile stretch of the then exposed continental shelf before discharging into the Gulf. (See maps in: Fisk and McFarlan, 1955, figure 4; Curray, 1965, figure 19a; Kane, 1959, figure 2). Kane's map of the oxidized zone at the top of the Beaumont Clay showed that the entrenched valleys of the Neches and Sabine Rivers joined under the present site of Sabine Lake (Figure 23). The sediments deposited since the beginning of the Holocene are those that lie above this marker horizon, which extends beneath the land areas and continues as an unconformity beneath the continental shelf. (See Bernard and LeBlanc, 1965, p. 150, 177-179; Curray, 1965, p. 733).

The time of the lowest sea level during the mid-Wisconsin has been estimated as more than 25,000 years ago by Bernard and LeBlanc (1965, p. 149) and about 18,000 years ago by Curray (1965, p. 723-724).

Sea level rose to its present level perhaps 3,000 to 5,000 years ago and has remained at about the same level. The various coastal features of Holocene age, seaward of the outcrop of the Beaumont Clay, are all less than 5,000 years old. Trinity Bay and Sabine Lake are essentially drowned valleys of the entrenched Pleistocene Trinity and Neches Rivers.

A few recent concepts and reformulations of the glacial stratigraphy and history of the midwestern United States have pointed up some areas where Fisk's theories seem to need revision; see Flint (1963), Frye and Willman (1960), Frye, Willman, and Black (1965), Frye and Leonard (1965), Curray (1965), Frye and Leonard (1953), Bernard and LeBlanc (1965), Durham (1965), Aten (1966a, 1966b), and Aronow (1967).

The Pleistocene history of the western Gulf Coast in general and of Chambers and Jefferson Counties in particular is far from worked out in detail, and much work remains to be done.

CONCLUSIONS AND RECOMMENDATIONS

Only small supplies of fresh ground water exist in the aquifers in Chambers and Jefferson Counties. Most of the fresh water used is surface water from the Trinity and Neches Rivers. Fifty-two percent of the ground water used is imported from neighboring counties. Large quantities of fresh ground water are available in adjoining counties and any large-scale demand for fresh ground water will likely be met by additional importation. Except for Beaumont's planned expansion of its well field in Hardin County, most future water needs will probably be met by surface-water supplies. Additional small fresh water supplies can be developed in Chambers and Jefferson Counties, but this development should be preceded by a careful program of testing and evaluation.

To fully utilize available ground water, the observation-well program in Chambers and Jefferson Counties to obtain data on both quality of water and water levels should not only be continued, but expanded and combined with the programs in adjacent counties. At present, the observation-well program in Chambers and Jefferson Counties covers only parts of the area. The expansion of this program should consider the planned increase of pumpage in Hardin County as well as anticipated increases in other counties. New wells should be continually inventoried, and aquifer tests should be made on the new wells to obtain additional information on the hydraulic properties of the aquifers. Collection of water samples should be expanded to monitor salt movement in all areas. Detailed observation of water levels and water quality in the vicinity of the salt domes, particularly in the vicinity of Mont Belvieu, is needed in

order to more precisely define and predict the movement of water in these areas of salinization.

Subsidence, as related to ground-water production, is, and will likely remain, a minor problem because additional development will probably be limited. Water levels will probably continue to be lowered by pumping in adjacent counties. However, data derived from measurements of subsidence when used with geologic and hydrologic data are useful in determining maximum water availability. This type of data has been used in the construction of analog models in this area. Also, knowledge of amount and rate of subsidence is important in planning surface drainage and water transfer facilities. Thus, an expanded program for measuring subsidence is needed in Chambers and Jefferson Counties. Further delay in starting such a program may prevent accurate determination of total subsidence and rates of subsidence. An enlarged network of bench marks should be established and leveled periodically. This program should be in conjunction with the program for the collection of water-level and pumpage records, so that correlations of cause and effect of subsidence can be made in the future.

Electrical-analog models are useful in the evaluation of aquifers. Such a model has been completed for the aquifers of the Houston district (Wood and Gabrysch, 1965). A preliminary model of the Chicot and Evangeline aquifers in southeast Texas and southwest Louisiana, including Chambers and Jefferson Counties, has been constructed. The program recommended above will provide data that could be used to improve the models and aid in the proper planning and development of the ground-water resources of Chambers and Jefferson Counties.
